BRIEF CONTENTS

About the Authors iv

PART ONE

ORGANIZATION OF THE BODY 1

- 1 Major Themes of Anatomy and Physiology 1
ATLAS A General Orientation to Human Anatomy 27
- 2 The Chemistry of Life 40
- 3 Cellular Form and Function 73
- 4 Genes and Cellular Function 106
- 5 The Human Tissues 135

PART TWO

SUPPORT AND MOVEMENT 172

- 6 The Integumentary System 172
- 7 Bone Tissue 196
- 8 The Skeletal System 221
- 9 Joints 265
- 10 The Muscular System 297
ATLAS B Regional and Surface Anatomy 360
- 11 Muscular Tissue 382

PART THREE

INTERNAL COORDINATION AND CONTROL 418

- 12 Nervous Tissue 418
- 13 The Spinal Cord, Spinal Nerves, and Somatic Reflexes 457
- 14 The Brain and Cranial Nerves 490
- 15 The Autonomic Nervous System and Visceral Reflexes 540
- 16 Sense Organs 561
- 17 The Endocrine System 610

PART FOUR

CIRCULATION AND DEFENSE 653

- 18 The Circulatory System: Blood 653
- 19 The Circulatory System: Heart 687
- 20 The Circulatory System: Blood Vessels and Circulation 722
- 21 The Lymphoid and Immune Systems 780

PART FIVE

INTAKE AND OUTPUT 825

- 22 The Respiratory System 825
- 23 The Urinary System 866
- 24 Fluid, Electrolyte, and Acid–Base Balance 901
- 25 The Digestive System 925
- 26 Nutrition and Metabolism 974

PART SIX

REPRODUCTION AND THE LIFE CYCLE 1007

- 27 The Male Reproductive System 1007
- 28 The Female Reproductive System 1037
- 29 Human Development and Aging 1075

APPENDIX A: Answer Keys A-1

APPENDIX B: Symbols, Weights, and Measures A-14

APPENDIX C: Periodic Table of the Elements A-16

APPENDIX D: The Genetic Code and Amino Acids A-17

APPENDIX E: Medical Word Roots and Affixes A-19

ABOUT THE AUTHORS

C. Diane Saladin

KENNETH S. SALADIN is Distinguished Professor of Biology, Emeritus, at Georgia College in Milledgeville, Georgia. He received his B.S. in zoology at Michigan State University and a Ph.D. in parasitology at Florida State University, with interests especially in the sensory ecology of freshwater invertebrates. He joined the Georgia College faculty in 1977 and taught courses there for 40 years, including human anatomy and physiology, introduction to medical physiology, histology, general zoology, parasitology, animal behavior, biomedical etymology, study abroad in the Galápagos Islands, and premedical seminars, among others. Ken has received numerous awards for research, teaching, and student mentoring. He received the university's Excellence in Research and Publication Award for the first edition of this book, and was named Distinguished Professor in 2001. Ken is a member of the Human Anatomy and Physiology Society, American Association for Anatomy, American Physiological Society, Society for Integrative and Comparative Biology, and Textbook and Academic Authors Association. Ken has used the earnings from his textbooks to support the Charles Darwin Research Station and fund ecosystem conservation and restoration in the Galápagos Islands, and to create endowments for the university's Honors College, the William Harvey Chair in Biomedical Science, the Annual William Harvey Lecture in Medicine and Society, the William P. Wall Museum of Natural History, the Saladin Endowment for Faculty-Mentored Student Research, and numerous scholarships. In retirement from the classroom, Ken continues to write his market-leading textbooks and mentor younger authors.

Yuen Lui Studios/Chris Gan

CHRISTINA A. GAN, digital author for Connect®, has been teaching anatomy and physiology, microbiology, and general biology at Highline College in Des Moines, Washington, since 2004. Before that, she taught at Rogue Community College in Medford, Oregon, for 6 years. She earned her M.A. in biology from Humboldt State University, researching the genetic variation of mitochondrial DNA in various salmonid species, and is a member of the Human Anatomy and Physiology Society. When she is not in the classroom or developing digital media, she is climbing, mountaineering, skiing, kayaking, sailing, cycling, and mountain biking throughout the Pacific Northwest.

THE EVOLUTION OF A STORYTELLER

Courtesy of Ken Saladin

Courtesy of Ken Saladin

Ken Saladin's first step into authoring was a 318-page paper on the ecology of hydras written for his tenth-grade biology class. With his "first book," featuring 53 original India ink drawings and photomicrographs, a true storyteller was born.

When I first became a textbook writer, I found myself bringing the same enjoyment of writing and illustrating to this book that I first discovered when I was 15.

—Ken Saladin

Ken's "first book," *Hydra Ecology*, 1965

Courtesy of Ken Saladin

One of Ken's drawings from *Hydra Ecology*

Courtesy of Ken Saladin

Ken began working on his first book for McGraw Hill in 1993, and in 1997 the first edition of *The Unity of Form and Function* was published. In 2023, the story continues with the tenth edition of Ken's best-selling A&P textbook.

The first edition (1997)

The story continues (2023)
McGraw Hill

PREFACE

Anatomy & Physiology: The Unity of Form and Function tells a story composed of many layers, including core science, clinical applications, the history of medicine, and the evolution of the human body. Saladin combines these perspectives on anatomy and physiology with vibrant photos and art to convey the beauty and excitement of the subject to beginning students.

To help students manage the tremendous amount of information in this introductory course, the narrative is broken into short segments, each framed by expected learning outcomes and self-testing review questions. This presentation strategy works as a whole to create a more efficient and effective way for students to learn A&P.

Saladin writes in a relaxed, slightly colloquial style to engage student interest and author–reader rapport; many have emailed him with appreciation for this, saying things like “It feels like you’re in the room talking to me personally.” Word choice and paragraph structure are aimed at an appropriate reading level for all students.

CHANGES TO THE TENTH EDITION

New Science

Content updates in this edition include new diagnostic uses of PET scans; anatomy of the mesentery; ciliary motility; improving life expectancy of chronic diseases; mitochondrial and chromosomal ancestries; genetic mosaicism in fetuses, adult brains, and somatic cells; brown adipose tissue; stem-cell research and regenerative medicine; evolution of skin color; appearance of pathological skin colors in people of brown and black complexions; function of the “prune fingers” effect; melanoma; endocrine functions of bone and muscle; osteopenia; muscle and microtrauma repair; the enteric nerve plexus; retrograde synaptic communication; the glymphatic system of the brain; the role of lamellar corpuscles of the feet in locomotion; several aspects of the sense of taste; pathways of visual information processing; the widening scope of the endocrine system; ethnic variations in blood type; erythrocyte and neutrophil functions; coronary artery disease and atheroma pathogenesis; C-reactive protein and inflammation; COVID-19; alveolar number and structure; E-cigarettes and vaping; dental proprioception; newly discovered functions of saliva and gastric mucus; the colonic microbiome; colon cancer; obesity; infant thermogenesis; heatstroke and heat exhaustion; nonbinary gender and intersexuality; spermatogenesis; clitoral function; the overlapping waves of oogenesis; lactation and bone density; research on male contraceptives; gamete migration; the site and mechanism of fertilization; updates on assisted reproductive technology; and theories of aging.

New Art and Photography

Numerous figures have improved labels, leaders, colors, and other details to aid readers with variations in visual acuity and color vision, and for better visibility of details in classroom projection. The art in this edition now represents a greater diversity in skin color, ethnicity, and cultural geography.

New and significantly modified drawings include the geographic distribution of skin color, cranial versus facial bone groups, sarcomere cross sections, divisions of the nervous system, ion distribution and movements in electrophysiology, dual autonomic control of the iris, visual processing streams in the brain, use of a sphygmomanometer, the glymphatic system of the brain, bacterial agglutination, the COVID coronavirus structure and mode of invasion, hemodialysis, lipoprotein structure, spermatogenesis, follicle cohort overlaps in folliculogenesis, gamete transport and the locus of fertilization, and the fertilization process.

New photographs include comminuted bone fractures, insulin discoverers Banting and Best, atherosclerotic plaques, lung histology, COVID lung, colon cancer, effects of alcoholism on the brain, and ovarian histology.

Diversity, Equity, and Inclusiveness

Previous editions consciously aimed for ethnic balance in art and language, but the tenth edition has received even closer attention to ethnic and cultural diversity, color, and the gender spectrum. It addresses the inadequately diverse representation seen in many textbooks in hopes that all readers will feel a sense of inclusion and familiarity. In the language of ethnicity, “race,” and color, this edition follows the recent guidelines of the American Medical Association and American Psychological Association. Gender-specific pronouns and nouns have been minimized, balanced where some remain, and deleted where they added nothing to the meaning of the writing. Discussions in genetics (chapter 4), endocrinology (chapter 17), and reproductive anatomy (chapter 27) now describe several biological reasons why people cannot be simply classified as male or female anatomically, physiologically, or behaviorally.

Major Changes by Chapter

The book before you has over 1,600 changes from the ninth edition—more than 500 updates in scientific content, nearly that many changes in the art and photography, and more than 600 changes in writing style and organization for ever-better flow and accessibility to the student reader. They cannot all be listed here, but these are some of the stand-out changes in each chapter.

Chapter 1, Major Themes of Anatomy and Physiology, adds female physician–author Metrodora to the otherwise male-dominated early history of medicine, and describes advances in PET scanning for early diagnosis of Alzheimer disease.

Atlas A, General Orientation to Human Anatomy, presents a new perspective on the mesentery.

Chapter 2, The Chemistry of Life, deletes some common misconceptions of atomic structure and chemical bonds.

Chapter 3, Cellular Form and Function, updates ciliary motility and mitochondrial functions, corrects a popular misconception about mitochondrial Eve, adds male chromosomal ancestry, and updates cystic fibrosis life expectancy.

Chapter 4, Genes and Cellular Function, corrects a myth about somatic cells being genetically identical, replaces cleft chin with sickle-cell disease for a more valid example of Punnett-square analysis of heredity, updates the genetics of the X and Y chromosomes, and adds a chromosomal explanation of gender variation.

Chapter 5, The Human Tissues, expands on the thermoregulatory significance of brown adipose tissue and updates the status of stem-cell research and regenerative medicine.

Chapter 6, The Integumentary System, has a new section on the forms of melanin and a new essay on evolution of skin color. It gives a better account of black and brown complexions in the recognition of cyanosis, pallor, and other pathological colors. It updates the physiological and functional perspectives on skin wrinkling in the “prune fingers” effect, inheritance of hair color, and several aspects of melanoma. Epidermal dendritic cells are now more accurately depicted in size and number in figure 6.3.

Chapter 7, Bone Tissue, includes the endocrine role of bone, new research on intramembranous ossification, a new discussion of osteopenia, and new X-rays of a comminuted clavicular fracture and surgical repair of a tibial plateau fracture.

Chapter 8, The Skeletal System, has extensively reorganized the labeling of skeletal anatomy, especially of the skull, and deleted the use of color keys to identify the bones. It adds a new figure distinguishing the facial and cranial bone groups. A misguided use of British spellings for some bone features (from *Gray’s Anatomy*) has been corrected to use the American spellings.

Chapter 10, The Muscular System, adds the endocrine role of muscles and improves the description of muscle fascicles.

Chapter 11, Muscular Tissue, notes the astounding number of nuclei per muscle cell; describes their action, and that of satellite cells, in repairing muscle microtrauma; describes the unusual arrangement of deep muscle mitochondria; updates the description of sarcomeres and now illustrates thin and thick myofilament arrangements in sarcomere cross sections; has new details on motor units; and updates muscular dystrophy.

Chapter 12, Nervous Tissue, now interprets the enteric plexus as a third branch of the autonomic nervous system in its own right. New information is added on the genetic mosaicism of neurons and the neuron-to-neuroglia ratio. Synapse structure is explained more fully, including the cell-adhesion molecules holding the pre- and postsynaptic neurons together, and a new TEM photograph of a synapse is added. New information is added on two-way communication across synapses and on the gut microbiome as a source of neurotransmitters. Electrophysiology figures 12.12 to 12.15 are modified for better visibility of the ions in classroom projection and to show charge changes on the neuronal membrane.

Chapter 13, The Spinal Cord, Spinal Nerves, and Somatic Reflexes, has brief factual additions on spinal taps, perineurium composition, and spinal cord injury statistics.

Chapter 14, The Brain and Cranial Nerves, defines CNS *nuclei* more explicitly and introduces new facts on meningitis, the number of brain neurons, the functions of CSF and sleep, the amygdala, aphasia, the oculomotor and trigeminal nerves, and motor fibers in the optic nerve. It has a new section on a surprising new finding, the brain’s glymphatic system, linking brain CSF and tissue fluid to the lymphoid and immune systems. Reversing a decision in previous editions, cranial nerve classification has reverted to the traditional designations identifying motor nerves as such, and not mixed, notwithstanding their inclusion of proprioceptive fibers.

Chapter 15, The Autonomic Nervous System, now describes the enteric plexus better and treats it as a third division of the ANS rather than part of the parasympathetic division; orthostatic hypotension is added to the end-of-chapter table of autonomic disorders; and the figure of dual autonomic control of the iris is improved.

Chapter 16, Sense Organs, better distinguishes sensation from perception; adds to the importance of lamellar corpuscles of the feet for coordinated standing and walking; adds a more standard definition of pain; has several additions on the sense of taste; adds evolutionary

perspectives on taste, smell, and the communication role of eyebrows; corrects the blood supply to the retina and the numbers of rod and cone cells; and better explains how the retina is held firmly against the choroid. It has a new figure of the dorsal and ventral streams of visual information processing.

Chapter 17, The Endocrine System, updates the meaning and scope of the endocrine system, corrects a common misconception on the name of the pineal gland, corrects the innervation of the pineal gland, and adds the endocrine role of skeletal muscles and a paternal role of oxytocin.

Chapter 18, The Circulatory System: Blood, adds the role of RBCs in immune clearance and non-mendelian inheritance of blood types, and explains seemingly incongruous parent–offspring blood-type disparities. It updates modes of iron loss from the body, genetic translation in mature RBCs, RBC senescence and disposal, sickle-cell disease, ethnic differences in blood type distribution, and leukemia treatment and survival.

Chapter 19, The Circulatory System: Heart, discusses variability in the number of cusps of the AV valves and substantially rewrites coronary artery disease, with a better explanation of atheroma formation and structure.

Chapter 20, The Circulatory System: Blood Vessels and Circulation, updates tumor angiogenesis inhibitors, has a new figure of sphygmomanometer use, and adds arteriovenous malformation to the table of vascular disorders.

Chapter 21, The Lymphoid and Immune Systems, changes the name of the system and its organs and tissues to *lymphoid*, using *lymphatic* only for the vessels. It has new sections on COVID-19 and on the newly discovered brain–lymphoid–immune system connection, the glymphatic system. It adds implications of thymic involution to immune responses in the elderly; the concept of immunosenescence; the neutrophil extracellular trap and eosinophil toxins as immune defenses; the role of C-reactive protein and its diagnostic value in inflammation; and the mechanism of splenic removal of senescent RBCs. It has new artwork for the glymphatic system, bacterial agglutination, and the SARS-CoV-2 virus and its mode of invasion.

Chapter 22, The Respiratory System, has further information on the nasal cycle of breathing and its contribution to olfaction; Ondine’s curse; the role of the lungs in platelet production; vaping and lung disease; and pulmonary blood circulation. It updates the number and structure of pulmonary alveoli and has new LM and SEM photos of lung histology.

Chapter 23, The Urinary System, has an improved image of hemodialysis.

Chapter 25, The Digestive System, has a new perspective on mesenteric anatomy. It expands the coverage of dental proprioception, salivary functions, and other aspects of oral health; the roles of gastric mucus and dendritic cells in promoting tolerance of food antigens and beneficial bacteria; colorectal cancer (with a new photo); the colonic microbiome; and Crohn disease and ulcerative colitis.

Chapter 26, Nutrition and Metabolism, updates the essay on obesity and body mass index. It corrects a misconception about caloric yield from carbohydrates and fats, deletes obsolete information about dietary cholesterol, and improves the illustration of lipoprotein structure. It adds information on infant thermoregulation and brown adipose tissue, clarifies the pathology of heatstroke and heat exhaustion, improves the language of alcoholism, and adds an MRI image of the effect of chronic alcohol abuse on the brain.

Chapter 27, The Male Reproductive System, has a new section (27.1e) on biological bases of gender and intersex, and a rewrite on aging and male sexual function. It adds explanations of scrotum evolution, the blood–testis barrier, the intercellular bridges between spermatogenic cells, formation of the acrosome, the timetable of spermatogenesis, involvement of seminiferous tubule peristalsis in sperm flow to the epididymis, and the role of the corpus spongiosum in maintaining urethral patency in erection. It updates information on testicular cancer and human papillomavirus. A figure of spermatogenesis in relation to the nurse cells is now correlated with a simpler flowchart of basic steps of the process.

Chapter 28, The Female Reproductive System, adds information on variants in uterine position, the importance of uterine cilia, the role of the clitoris and female orgasm in semen retention and conception, the relevance of morning sickness to fetal health, fetal signaling of readiness to be born, breast-feeding benefits to maternal bone density, and the problems in developing a chemical contraceptive for males. It has new figures of ovarian histology and the timetable and overlap of cohorts of developing ovarian follicles, with explanation relating the 290-day follicular maturation timetable to the 28-day rhythm of ovulation.

Chapter 29, Human Development and Aging, has a thorough rewrite on new understandings of gamete migration, sperm capacitation, and fertilization, with revised illustrations to dispense with common misconceptions and agree with newer literature. This chapter now offers new or enhanced discussions of senescence of the cornea; thymic involution and immunity in old age; telomere theory; COVID-19 changing mortality and life expectancy statistics; and concepts of clinical death. The final chapter essay updates information on assisted reproductive technologies.

ACKNOWLEDGMENTS

Peer review is a critical part of the scientific process, and very important to ensure the content in this book continues to meet the needs of the instructors and students who use it. I am grateful for the people who agree to participate in this process and thank them for their time, talents, and feedback. The reviewers of this text, listed here, contributed significant comments that helped us refine and update the print and digital components of this program.

I especially thank Dr. Justin York of Glendale Community College, Glendale, Arizona. Justin analyzed the entire book in fine detail and made innumerable insightful suggestions on scientific content, organization, writing style, art, photography, and Instructor PowerPoints. Much of the improvement in this edition is owing to Justin's input.

I also owe a great deal to spontaneous emails from colleagues and students worldwide telling me what they've liked about the book and what could be improved, and alerting me to needed corrections. I'm also indebted to many fruitful discussions on the HAPS-L listserve of the Human Anatomy and Physiology Society and to anatomists, physiologists, physicians, and other experts I've gotten to know on Quora.com, who have provided so many helpful ideas and supportive literature citations to new developments in A&P.

Christina Gan updated the question bank and test bank to closely correlate with

the many changes made in this tenth edition and greatly enhanced the educational value of this book through her work to create self-assessment tools and align McGraw Hill's Connect resources with the textbook. Christina's work has contributed significantly to student and instructor satisfaction with our overall package of learning media, and to students' success as they navigate the learning challenges of A&P en route to their career goals.

I also extend my deep appreciation to the Life Sciences Book Team at McGraw Hill who worked with me on this project: Matthew Garcia, Executive Portfolio Manager; Monica Lewis, Marketing Manager; Melisa Seegmiller, Senior Product Developer; Vicki Krug, Senior Content Project Manager; Brent dela Cruz, Lead Assessment Content Project Manager; Lori Hancock, Senior Content Licensing Specialist; David Hash, Lead Designer; and Mike McGee, freelance copy editor.

DEDICATION

I dedicate this book to

Colin Wheatley

for recognizing 30 years ago that I had a book in me,
and laying the bedrock of my textbook writing career.

THE STORY OF FORM AND FUNCTION

INNOVATIVE CHAPTER SEQUENCING

Some chapters and topics are presented in a sequence that is more instructive than the conventional order.

Early Presentation of Heredity

Fundamental principles of heredity are presented in the last few pages of chapter 4 rather than at the back of the book to better integrate molecular and Mendelian genetics. This organization also prepares students to learn about such genetic traits and conditions as cystic fibrosis, color blindness, blood types, hemophilia, cancer genes, and sickle-cell disease by first teaching them about dominant and recessive alleles, genotype and phenotype, and sex linkage.

Urinary System Presented Close to Circulatory and Respiratory Systems

Most textbooks place this system near the end of the book because of its anatomical and developmental relationships with the reproductive system. However, its physiological ties to the circulatory and respiratory systems are much more important. Except for a necessary digression on lymphatics and immunity, the circulatory system is followed almost immediately with the respiratory and urinary systems, which regulate blood composition and whose functional mechanisms rely on recently covered principles of blood flow and capillary exchange.

Muscle Anatomy and Physiology Follow Skeleton and Joints

The functional morphology of the skeleton, joints, and muscles is treated in three consecutive chapters, 8 through 10, so when students learn muscle attachments, these come only two chapters after the names of the relevant bone features. When they learn muscle actions, it is in the first chapter after learning the terms for the joint movements. This order brings another advantage: The physiology of muscle and nerve cells is treated in two consecutive chapters (11 and 12), which are thus closely integrated in their treatment of synapses, neurotransmitters, and membrane electrophysiology.

THE STORY OF FORM AND FUNCTION

LEARNING TOOLS

Engaging Chapter Layouts

- Chapters are structured around the way students learn.
- Frequent subheadings and expected learning outcomes help students plan their study time and review strategies.

Deeper Insights highlight areas of interest and career relevance for students.

Chapter Outlines provide quick previews of the content.

74 PART ONE Organization of the Body

BRUSHING UP

- The transport of matter through cell membranes follows the principles of flow down gradients (see section 1.6e).
- To adequately understand the structure of the cell surface, it is essential that you understand glycolipids and glycoproteins, as well as phospholipids and their amphipathic nature (see sections 2.4c and 2.4d).
- The proteins of cell membranes have a great variety of functions. To understand those depends on an acquaintance with the functions of proteins in general and how protein function depends on tertiary structure (see "Protein Structure" and "Protein Functions" in section 2.4e).

All organisms, from the simplest to the most complex, are composed of cells—whether the single cell of a bacterium or the trillions of cells that constitute the human body. These cells are responsible for all structural and functional properties of a living organism. A knowledge of cells is therefore indispensable to any true understanding of the workings of the human body, the mechanisms of disease, and the rationale of therapy. Thus, this chapter and the next one introduce the basic cell biology of the human body, and subsequent chapters expand upon this information as we examine the specialized cellular structure and function of specific organs.

3.1 Concepts of Cellular Structure

Expected Learning Outcomes

When you have completed this section, you should be able to

- discuss the development and modern tenets of the cell theory;
- describe cell shapes from their descriptive terms;
- state the size range of human cells and discuss factors that limit their size;
- discuss the way that developments in microscopy have changed our view of cell structure; and
- outline the major components of a cell.

3.1a Development of the Cell Theory

Cytology,¹ the scientific study of cells, was born in 1663, when Robert Hooke observed the empty cell walls of cork and coined the word *cellulae* ("little cells") to describe them (see section 1.2). Soon he studied thin slices of fresh wood and saw living cells

"filled with juices"—a fluid later named *cytoplasm*. By the mid-1800s, with increasingly sophisticated instruments and methods of observation, scientists arrived at certain generalizations about cells that we now call the **cell theory**. This is credited especially to German physician-physiologist Theodor Schwann (1810–82) and German botanist Matthias Schleiden (1804–81). Although stated in various ways, the most essential points of the cell theory are:

- All living organisms are made of one or more cells.
- Cells are the basic structural and functional units of all living organisms. Nothing simpler than a cell, such as an organelle, DNA, or an enzyme, is alive in itself.
- All activities of an organism (including the human body) stem from the activities of its constituent cells. Cytology is therefore the foundation for all biological understanding of life.
- All cells arise from preexisting cells, not from nonliving matter, and they pass hereditary information from generation to generation of cells.

3.1b Cell Shapes and Sizes

We will shortly examine the structure of a generic cell, but the generalizations we draw shouldn't blind you to the diversity of cellular form and function in humans. There are about 200 kinds of cells in the human body, with a variety of shapes, sizes, and functions.

Descriptions of organ and tissue structure often refer to the shapes of cells by the following terms (fig. 3.1):

- **Squamous**² (SKWAY-mus)—a thin, flat, scaly shape, often with a bulge where the nucleus is, much like the shape of a fried egg "sunny side up." Squamous cells line the esophagus and air sacs (alveoli) of the lungs, and form the surface layer (epidermis) of the skin.
- **Cuboidal**³ (cue-BOY-dul)—squarish-looking in frontal sections and about equal in height and width; liver cells are a good example.
- **Columnar**—distinctly taller than wide, such as the inner lining cells of the stomach and intestines.
- **Polygonal**⁴—having irregularly angular shapes with four, five, or more sides, like the wax cells of a honeycomb. The densely packed cells of many glands are polygonal.
- **Stellate**⁵—having multiple pointed processes projecting from the body of a cell, giving it a somewhat starlike shape. The cell bodies of many nerve cells are stellate.

²squum = scale; mus = characterized by
³cub = cube; oid = like, resembling
⁴poly = many; gon = angles
⁵stell = star; ate = resembling, characterized by

¹cyto = cell; logy = study of

CHAPTER 7

BONE TISSUE

A bone cell (osteocyte) surrounded by calcified bone matrix.
Eye of Science/S Science Source

CHAPTER OUTLINE

- 7.1 Tissues and Organs of the Skeletal System
 - 7.1a Functions of the Skeleton
 - 7.1b Bones and Osseous Tissue
 - 7.1c General Features of Bones
- 7.2 Histology of Osseous Tissue
 - 7.2a Bone Cells
 - 7.2b The Matrix
 - 7.2c Compact Bone
 - 7.2d Spongy Bone
 - 7.2e Bone Marrow
- 7.3 Bone Development
 - 7.3a Intramembranous Ossification
 - 7.3b Endochondral Ossification
 - 7.3c Bone Growth and Remodeling

7.4 Physiology of Osseous Tissue

- 7.4a Mineral Deposition and Resorption
 - 7.4b Calcium Homeostasis
 - 7.4c Phosphate Homeostasis
 - 7.4d Other Factors Affecting Bone
- 7.5 Bone Disorders
- 7.5a Fractures and Their Repair
 - 7.5b Other Bone Disorders
- System Connections
Study Guide

DEEPER INSIGHTS

- 7.1 Medical History: Bone Contamination
- 7.2 Clinical Application: Achondroplastic Dwarfism
- 7.3 Clinical Application: Rickets and Osteomalacia
- 7.4 Clinical Application: Osteopenia and Osteoporosis

Anatomy & Physiology
Revealed 4.0
Module 5: Skeletal System

Tiered Assessments Based on Key Learning Outcomes

- Chapters are divided into brief sections, enabling students to set specific goals for short study periods.
- Section-ending questions allow students to check their understanding before moving on.

Each chapter begins with **Brushing Up** to emphasize the interrelatedness of concepts, which is especially useful for adult students returning to the classroom, and serves as an aid for instructors when teaching chapters out of order.

Each major section begins with **Expected Learning Outcomes** to help focus the reader's attention on the larger concepts and make the course outcome-driven. This also assists instructors in structuring their courses around expected learning outcomes.

Questions in figure legends and **Apply What You Know** items prompt students to think more deeply about the implications and applications of what they have learned. This helps students practice higher-order thinking skills throughout the chapter.

separation between the bones and length of the fibers give these joints more mobility than a suture or gomphosis has. An especially mobile syndesmosis exists between the shafts of the radius and ulna, which are joined by a broad fibrous *interosseous membrane*. This permits such movements as pronation and supination of the forearm. A less mobile syndesmosis is the one that binds the distal ends of the tibia and fibula together, side by side (see fig. 9.2c).

9.1c Cartilaginous Joints

A **cartilaginous joint** is also called an **amphiarthrosis**¹ (AM-fear-THRO-sis). In these joints, two bones are linked by cartilage (fig. 9.4). The two types of cartilaginous joints are **synchondroses** and **symphyses**.

Synchondroses

A **synchondrosis**² (SIN-con-DRO-sis) is a joint in which the bones are joined by hyaline cartilage. An example is the temporary joint between the epiphysis and diaphysis of a long bone in a child, formed by the cartilage of the epiphyseal plate. Another is the attachment of the first rib to the sternum by a hyaline costal cartilage

(fig. 9.4a). (The other costal cartilages are joined to the sternum by synovial joints.)

Symphyses

In a **symphysis**³ (SIM-fih-sis), two bones are joined by fibrocartilage (fig. 9.4b, c). One example is the pubic symphysis, in which the right and left pubic bones are joined anteriorly by the cartilaginous interpubic disc. Another is the joint between the bodies of two vertebrae, united by an intervertebral disc. The surface of each vertebral body is covered with hyaline cartilage. Between the vertebrae, this cartilage becomes infiltrated with collagen bundles to form fibrocartilage. Each intervertebral disc permits only slight movement between adjacent vertebrae, but the collective effect of all 23 discs gives the spine considerable flexibility.

APPLY WHAT YOU KNOW

The intervertebral joints are symphyses only in the cervical through the lumbar region. How would you classify the intervertebral joints of the sacrum and coccyx in a middle-aged adult?

¹amphi = on all sides; arthro = jointed; -osis = condition
²syn = together; chondr = cartilage; -osis = condition
³sym = together; physis = growth

FIGURE 9.4 Cartilaginous Joints.

(a) A synchondrosis, represented by the costal cartilage joining rib 1 to the sternum. (b) The pubic symphysis. (c) Intervertebral discs, which join adjacent vertebrae to each other by symphyses.

What is the difference between the pubic symphysis and the interpubic disc?

The end-of-chapter **Study Guide** offers several methods for assessment that are useful to both students and instructors.

Assess Your Learning Outcomes provides students a study outline for review, and addresses the needs of instructors whose colleges require outcome-oriented syllabi and assessment of student achievement of the expected learning outcomes.

End-of-chapter questions build on all levels of Bloom's Taxonomy in sections to

1. test simple recall and analytical thought;
2. build medical vocabulary; and
3. apply the basic knowledge to new clinical problems and other situations.

What's Wrong with These Statements? questions further address Bloom's Taxonomy by asking the student to explain *why* the false statements are untrue.

Testing Your Comprehension questions address Bloom's Taxonomy in going beyond recall to application of ideas.

Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

9.1 Joints and Their Classification

1. The fundamental definition of joint (articulation) and why it can't be defined as a point at which one bone moves relative to an adjacent bone.
2. Three essential components of a lever.
3. The meaning of *mechanical advantage* (MA); how the MA of a lever can be determined from measurements of its effort and resistance arms; and the respective advantages of levers in which the MA is greater than or less than 1.0.
4. Comparison of first-, second-, and third-class levers, and anatomical examples of

12. The same for flexion, extension, hyperextension, and lateral flexion of the spine, and right and left rotation of the trunk.
13. The same for elevation, depression, protraction, retraction, and lateral and medial excursion of the mandible.
14. The same for dorsiflexion, plantar flexion, inversion, eversion, pronation, and supination of the foot.

Testing Your Recall

1. Internal and external rotation of the humerus is made possible by a _____ joint.
 - a. pivot
 - b. condylar
 - c. ball-and-socket
 - d. saddle
 - e. hinge
2. Which of the following is the least movable?
 - a. diarthrosis
 - b. a synostosis
 - c. a symphysis
 - d. a synovial joint
 - e. a condylar joint
3. Which of the following movements are unique to the foot?
 - a. dorsiflexion and inversion
 - b. elevation and depression
 - c. circumduction and rotation
 - d. abduction and adduction
 - e. opposition and reposition

Answers in Appendix A

Building Your Medical Vocabulary

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

1. ab-
2. arthro-
3. -ate
4. cruci-
5. cruro-
6. -disc
7. kinesi-
8. men-
9. supin-
10. -trac

Answers in Appendix A

What's Wrong with These Statements?

Briefly explain why each of the following statements is false, or reword it to make it true.

1. More people get rheumatoid arthritis than osteoarthritis.
2. A doctor who treats arthritis is called a kinesiologist.
3. Synovial joints are also known as synarthroses.
4. Menisci occur in the elbow and knee joints.
5. Reaching behind you to take something out of your hip pocket involves flexion of the shoulder.
6. The cruciate ligaments are in the feet.
7. The femur is held tightly in the acetabulum mainly by the round ligament.
8. The knuckles are amphiarthroses.
9. Synovial fluid is secreted by the bursae.
10. Like most ligaments, the periodontal ligaments attach one bone (the tooth) to another (the mandible or maxilla).

Answers in Appendix A

STUDY GUIDE

Testing Your Comprehension

1. All second-class levers produce a mechanical advantage greater than 1.0 and all third-class levers produce a mechanical advantage less than 1.0. Explain why.
2. For each of the following joint movements, state what bone the axis of rotation passes through and which of the three anatomical planes contains the axis of rotation. You may find it helpful to produce some of these actions on an articulated laboratory skeleton so you can more easily visualize the axis of rotation. (a) Plantar flexion; (b) flexion of the hip; (c) abduction of the thigh; (d) flexion of the knee; (e) flexion of the first interphalangeal joint of the index finger. (Do not bend the fingers of a wired laboratory skeletal hand, because they can break off.)
3. In order of occurrence, list the joint actions (flexion, pronation, etc.) and the joints where they would occur as you (a) sit down at a table, (b) reach out and pick up an apple, (c) take a bite, and (d) chew it. Assume that you start in anatomical position.
4. The deltoid muscle inserts on the deltoid tuberosity of the humerus and abducts the arm. Imagine a person holding a weight in the hand and abducting the arm. On a laboratory skeleton, identify the fulcrum; measure the effort arm and resistance arm; determine the mechanical advantage of this movement; and determine which of the three lever types the upper limb acts as when performing this movement.
5. List the six types of synovial joints, and for each one, if possible, identify a joint in the upper limb and a joint in the lower limb that fall into each category. Which of these six joints have no examples in the lower limb?

THE STORY OF FORM AND FUNCTION

ARTWORK THAT INSPIRES LEARNING

The incredible art program in this textbook sets the standard in A&P. The stunning portfolio of art and photos was created with the aid of art focus groups and with feedback from hundreds of accuracy reviews.

Vivid Illustrations

Rich textures and shading and bold, bright colors bring structures to life.

Francis Leroy, Biocosmos/Science Source

Christine Eckel/McGraw Hill

Cadaver dissections are paired with carefully drawn illustrations to show intricate human detail.

Orientation Tools

Saladin art integrates tools to help students quickly orient themselves within a figure and make connections between ideas.

(a) Anterior view

(b) Cross section

Conducive to Learning

- Easy-to-understand process figures
- Tools for students to easily orient themselves

Process Figures

Saladin breaks complicated physiological processes into numbered steps for a manageable introduction to difficult concepts.

- 1 Blood enters right atrium from superior and inferior venae cavae.
- 2 Blood in right atrium flows through right AV valve into right ventricle.
- 3 Contraction of right ventricle forces pulmonary valve open.
- 4 Blood flows through pulmonary valve into pulmonary trunk.
- 5 Blood is distributed by right and left pulmonary arteries to the lungs, where it unloads CO_2 and loads O_2 .
- 6 Blood returns from lungs via pulmonary veins to left atrium.
- 7 Blood in left atrium flows through left AV valve into left ventricle.
- 8 Contraction of left ventricle (simultaneous with step 3) forces aortic valve open.
- 9 Blood flows through aortic valve into ascending aorta.
- 10 Blood in aorta is distributed to every organ in the body, where it unloads O_2 and loads CO_2 .
- 11 Blood returns to right atrium via venae cavae.

Everything you need in one place

Your Connect course has everything you need—whether reading your digital eBook or completing assignments for class, Connect makes it easy to get your work done.

Learning for everyone

McGraw Hill works directly with Accessibility Services Departments and faculty to meet the learning needs of all students. Please contact your Accessibility Services Office and ask them to email accessibility@mheducation.com, or visit mheducation.com/about/accessibility for more information.

McGraw Hill Connect® empowers students to learn and succeed in the Anatomy and Physiology course with user-friendly digital solutions.

Anatomy & Physiology Revealed (APR)

is an interactive cadaver dissection tool to enhance lecture and lab. Featuring real cadaver photography, animations, interactive 3D models, histology, imaging and more. Now assignable in Connect! **The result? Students are prepared for lab, engaged in the material, and utilize critical thinking.**

Virtual Labs helps connect the dots between lab and lecture, boosts student confidence and knowledge, and improves student success rates. Interactive animations and simulations also encourage students to explore key physiological processes and difficult concepts. **The result? Students are engaged, prepared, and utilize critical thinking skills.**

PracticeATLAS

Practice Atlas for A&P

is integrated into APR, pairing images of common anatomical models with stunning cadaver photography, which allows students to practice naming structures on both models and human bodies. **The result? Students are better prepared, engaged, and move beyond basic memorization.**

A&P Prep

A&P Prep helps students thrive in college-level A&P by helping solidify knowledge in the key areas of cell biology, chemistry, study skills, and math. **The result? Students are better prepared for the A&P course.**

PhILS

PhILS (Physiology Interactive Lab Simulations) is the perfect way to reinforce key physiology concepts with powerful lab experiments. **The result? Students gain critical thinking skills and are better prepared for lab.**

SmartBook®

SmartBook 2.0 provides personalized learning to individual student needs, continually adapting to pinpoint knowledge gaps and focus learning on concepts requiring additional study. **The result? Students are highly engaged in the content and better prepared for lecture.**

LETTER TO STUDENTS

When I was a young boy, I became interested in what I then called “nature study” for two reasons. One was the sheer beauty of nature. I reveled in children’s books with abundant, colorful drawings and photographs of animals, plants, minerals, and gems. It was this esthetic appreciation of nature that made me want to learn more about it and made me happily surprised to discover I could make a career of it. At a slightly later age, another thing that drew me still deeper into biology was to discover writers who had a way with words—who could captivate my imagination and curiosity with their elegant prose. Once I was old enough to hold part-time jobs, I began buying zoology and anatomy books that mesmerized me with their gracefulness of writing and fascinating art and photography. I wanted to write and draw like that myself, and I began teaching myself by learning from “the masters.” I spent many late nights in my room peering into my microscope and jars of pond water, typing page after page of manuscript, and trying pen and ink as an art medium. My “first book” was a 318-page paper on some little pond animals called hydras, with 53 India ink illustrations that I wrote for my tenth-grade biology class when I was 16 (see page viii).

Fast-forward about 30 years, to when I became a textbook writer, and I found myself bringing that same enjoyment of writing and illustrating to the first edition of this book you are now holding. Why? Not only for its intrinsic creative satisfaction, but because I’m guessing that you’re like I was—you can appreciate a book that does more than simply give you the information you need. You appreciate, I trust, writers who make it enjoyable for you through their scientific, storytelling prose and their concepts of the way things should be illustrated to spark interest and facilitate understanding.

I know from my own students, however, that you need more than captivating illustrations and enjoyable reading. Let’s face it—A&P is a complex subject and it may seem a formidable task to acquire even a basic knowledge of the human body. It was difficult even for me to learn (and the learning never ends). So in addition to simply writing this book, I’ve given a lot of thought to its

pedagogy—the art of teaching. I’ve designed my chapters to make them easier for you to study and to give you abundant opportunity to check whether you’ve understood what you read—to test yourself (as I always advised my own students) before the instructor tests you.

Each chapter is broken down into short, digestible bits with a set of Expected Learning Outcomes at the beginning of each section, and self-testing questions (Before You Go On) just a few pages later. Even if you have just 30 minutes to read during a lunch break or a bus ride, you can easily read or review one of these brief sections. There are also numerous self-testing questions in a Study Guide at the end of each chapter, in some of the figure legends, and Apply What You Know questions dispersed throughout each chapter. The questions cover a broad range of cognitive skills, from simple recall of a term to your ability to evaluate, analyze, and apply what you’ve learned to new clinical situations or other problems. In this era of digital publishing, however, learning aids go far beyond what I write into the book itself. SmartBook, available on smartphones and tablets, includes all of the book’s contents plus adaptive technology that can give you personalized instruction, target the unique gaps in your knowledge, and guide you in comprehension and retention of the subject matter.

I hope you enjoy your study of this book, but I know there are always ways to make it even better. Indeed, what quality you may find in this edition owes a great deal to feedback I’ve received from students all over the world. If you find any typos or other errors, if you have any suggestions for improvement, if I can clarify a concept for you, or even if you just want to comment on something you really like about the book, I hope you’ll feel free to write to me. I correspond quite often with students and would enjoy hearing from you.

- 1.5 Clinical Application: Medical Imaging

Module 1: Body Orientation

No branch of science hits as close to home as the science of our own bodies. We're grateful for the dependability of our hearts; we're awed by the capabilities of muscles and joints displayed by Olympic athletes; and we ponder with philosophers the ancient mysteries of mind and emotion. We want to know how our body works, and when it malfunctions, we want to know what's happening and what we can do about it. Even the most ancient writings of civilization include medical documents that attest to humanity's timeless drive to know itself. You are embarking on a subject that is as old as civilization, yet one that grows by thousands of scientific publications every week.

This book is an introduction to human structure and function, the biology of the human body. It is meant primarily to give you a foundation for advanced study in health care, exercise physiology, pathology, and other fields related to health and fitness. Beyond that purpose, however, it can also provide you with a deeply satisfying sense of self-understanding.

As rewarding and engrossing as this subject is, the human body is highly complex, and understanding it requires us to comprehend a great deal of detail. The details will be more manageable if we relate them to a few broad, unifying concepts. The aim of this chapter, therefore, is to introduce such concepts and put the rest of the book into perspective. We consider the historical development of anatomy and physiology, the thought processes that led to the knowledge in this book, the meaning of human life, some central concepts of physiology, and how to better understand medical terminology.

1.1 The Scope of Anatomy and Physiology

Expected Learning Outcomes

When you have completed this section, you should be able to

- define *anatomy* and *physiology* and relate them to each other;
- describe several ways of studying human anatomy; and
- define a few subdisciplines of human physiology.

Anatomy is the study of structure, and **physiology** is the study of function. These approaches are complementary and never entirely separable. Together, they form the bedrock of the health sciences. When we study a structure, we want to know, What does it do? Physiology lends meaning to anatomy, and conversely, anatomy is what makes physiology possible. This *unity of form and function* is an important point to bear in mind as you study the body. Many examples of it will be apparent throughout the book—some of them pointed out for you, and others you will notice for yourself.

1.1a Anatomy—The Study of Form

There are several ways to examine the structure of the human body. The simplest is **inspection**—simply looking at the body's appearance, as in performing a physical examination or making

a clinical diagnosis from surface appearance. Physical examinations also involve touching and listening to the body. **Palpation**¹ means feeling a structure with the hands, such as palpating a swollen lymph node or taking a pulse. **Auscultation**² (AWS-cul-TAY-shun) is listening to the natural sounds made by the body, such as heart and lung sounds. In **percussion**, the examiner taps on the body, feels for abnormal resistance, and listens to the emitted sound for signs of abnormalities such as pockets of fluid, air, or scar tissue.

But a deeper understanding of the body depends on **dissection** (dis-SEC-shun)—carefully cutting and separating tissues to reveal their relationships. The very words *anatomy*³ and *dissection*⁴ both mean “cutting apart”; until the nineteenth century, dissection was called “anatomizing.” In many schools of health science, one of the first steps in training students is dissection of the **cadaver**,⁵ a dead human body. Many insights into human structure are obtained from **comparative anatomy**—the study of multiple species in order to examine similarities and differences and analyze evolutionary trends. Anatomy students often begin by dissecting other animals with which we share a common ancestry and many structural similarities. Many of the reasons for human structure become apparent only when we look at the structure of other animals.

Dissection, of course, is not the method of choice when studying a living person! It was once common to diagnose disorders through **exploratory surgery**—opening the body and taking a look inside to see what was wrong and what could be done about it. Any breach of the body cavities is risky, however, and most exploratory surgery has now been replaced by **medical imaging** techniques—methods of viewing the inside of the body without surgery, discussed at the end of this chapter (see Deeper Insight 1.5). The branch of medicine concerned with imaging is called **radiology**. Structure that can be seen with the naked eye—whether by surface observation, radiology, or dissection—is called **gross anatomy**.

Ultimately, the functions of the body result from its individual cells. To see those, we usually take tissue specimens, thinly slice and stain them, and observe them under the microscope. This approach is called **histology**⁶ (**microscopic anatomy**). **Histopathology** is the microscopic examination of tissues for signs of disease. **Cytology**⁷ is the study of the structure and function of individual cells. **Ultrastructure** refers to fine detail, down to the molecular level, revealed by the electron microscope.

1.1b Physiology—The Study of Function

Physiology⁸ uses the methods of experimental science discussed later. It has many subdisciplines such as *neurophysiology* (physiology of the nervous system), *endocrinology* (physiology of

¹*palp* = touch, feel; *ation* = process

²*auscult* = listen; *ation* = process

³*ana* = apart; *tom* = cut

⁴*dis* = apart; *sect* = cut

⁵from *cadere* = to fall down or die

⁶*histo* = tissue; *logy* = study of

⁷*cyto* = cell; *logy* = study of

⁸*physio* = nature; *logy* = study of

hormones), and *pathophysiology* (mechanisms of disease). Partly because of limitations on experimentation with humans, much of what we know about bodily function has been gained through **comparative physiology**, the study of how different species have solved problems of life such as water balance, respiration, and reproduction. Comparative physiology is also the basis for the development of new drugs and medical procedures. For example, a cardiac surgeon may learn animal surgery before practicing on humans, and a vaccine cannot be used on human subjects until it has been demonstrated through animal research that it confers significant benefits without unacceptable risks.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. What is the difference between anatomy and physiology? How do these two sciences support each other?
2. Name the method that would be used for each of the following: listening to a patient for a heart murmur; studying the microscopic structure of the liver; microscopically examining liver tissue for signs of hepatitis; learning the blood vessels of a cadaver; and performing a breast self-examination.

1.2 The Origins of Biomedical Science

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. give examples of how modern biomedical science emerged from an era of superstition and authoritarianism; and
- b. describe the contributions of some key people who helped to bring about this transformation.

Any science is more enjoyable if we consider not just the current state of knowledge, but how it compares to past understandings of the subject and how our knowledge was gained. Of all sciences, medicine has one of the most fascinating histories. Medicine has progressed far more in the last 50 years than in the 2,500 years before that, but the field didn't spring up overnight. It is built upon centuries of thought and controversy, triumph and defeat. We cannot fully appreciate its present state without understanding its past—people who had the curiosity to try new things, the vision to look at human form and function in new ways, and the courage to question authority.

1.2a The Greek and Roman Legacy

As early as 3,000 years ago, physicians in Mesopotamia and Egypt treated patients with herbal drugs, salts, physical therapy, and faith healing. The “father of medicine,” however, is usually considered to be the Greek physician **Hippocrates**

(c. 460–c. 375 BCE). He and his followers established a code of ethics for physicians, the Hippocratic Oath, which is still recited in modern form by graduating physicians at some medical schools. Hippocrates urged physicians to stop attributing disease to the activities of gods and demons and to seek their natural causes, which could afford the only rational basis for therapy.

Aristotle (384–322 BCE) was one of the first philosophers to write about anatomy and physiology. He believed that diseases and other natural events could have either supernatural causes, which he called *theologi*, or natural ones, which he called *physici* or *physiologi*. We derive such terms as *physician* and *physiology* from the latter. Until the nineteenth century, physicians were called “doctors of physic.” In his anatomy book, *On the Parts of Animals*, Aristotle aimed to identify unifying themes in nature. Among other points, he argued that complex structures are built from a smaller variety of simple components—a perspective that we will find useful later in this chapter.

▶▶▶ APPLY WHAT YOU KNOW

When you have completed this chapter, discuss the relevance of Aristotle's philosophy to our current thinking about human structure.

Female physicians of ancient Greece and Rome were largely limited in their practice to gynecology and obstetrics. Among them, Greek physician **Metrodora** (c. 200 BCE) was perhaps the first woman to publish a medical textbook, the two-volume gynecological treatise *On the Diseases and Cures of Women*. It was widely translated and used in ancient Greece and Rome and used as late as 1597 CE in Europe.

Claudius Galen (129–c. 200), physician to the Roman gladiators, wrote the most influential medical textbook of the ancient era—a book worshipped to excess by medical professors for centuries to follow. Cadaver dissection was banned in Galen's time because of some horrid excesses that preceded him, including public dissection of living enslaved and imprisoned individuals. Aside from what he could learn by treating gladiators' wounds, Galen was therefore limited to dissecting pigs, monkeys, and other animals. Because he wasn't permitted to dissect cadavers, he had to guess at much of human anatomy and made some incorrect deductions from animal dissections. He described the human liver, for example, as having five fingerlike lobes because that's what he had seen in baboons. But Galen saw science as a method of discovery, not a body of fact to be taken on faith. He warned that even his own books could be wrong and advised his followers to trust their own observations more than any book. Unfortunately, his advice wasn't heeded. For nearly 1,500 years, medical professors dogmatically taught what they read in Aristotle and Galen, seldom daring to question the authority of these “ancient masters.”

1.2b The Birth of Modern Medicine

In the Middle Ages, the state of medical science varied greatly from one religious culture to another. Science was severely repressed in the Christian culture of Europe until about the sixteenth century, although some of the most famous medical schools of

Europe were founded during this era. Their professors, however, taught medicine primarily as a dogmatic commentary on Galen and Aristotle, not as a field of original research. Medieval medical illustrations were crude representations of the body intended more to decorate a page than to depict the body realistically (**fig. 1.1a**). Some were astrological charts that showed which sign of the zodiac was thought to influence each organ of the body. From such pseudoscience came the word *influenza*, Italian for “influence.”

Free inquiry was less inhibited in Jewish and Muslim culture during this time. Jewish physicians were the most esteemed practitioners of their art—and none more famous than *Moses ben Maimon* (1135–1204), known in Christendom as **Maimonides**. Born in Spain, he fled to Egypt at age 24 to escape antisemitic persecution. There he served the rest of his life as physician to the court of the sultan, Saladin. A highly admired rabbi, Maimonides wrote voluminously on Jewish law and theology, but also wrote

10 influential medical books and numerous treatises on specific diseases.

Among Muslims, probably the most highly regarded medical scholar was *Ibn Sina* (980–1037), known in the West as **Avicenna** or “the Galen of Islam.” He studied Galen and Aristotle, combined their findings with original discoveries, and questioned authority when the evidence demanded it. Medicine in the Mideast soon became superior to European medicine. Avicenna’s textbook, *The Canon of Medicine*, was a leading authority in European medical schools for over 500 years.

Chinese medicine had little influence on Western thought and practice until relatively recently; the medical arts evolved in China quite independently of European medicine. Later chapters of this book describe some of the insights of ancient China and India.

Modern Western medicine began around the sixteenth century in the innovative minds of such people as the anatomist Andreas

(a)

(b)

FIGURE 1.1 The Evolution of Medical Art. Two illustrations of the skeletal system made about 500 years apart. (a) From an eleventh-century work attributed to Persian physician Avicenna. (b) From *De Humani Corporis Fabrica* by Andreas Vesalius, 1543.

Vesalius and the physiologist William Harvey. **Andreas Vesalius** (1514–64) taught anatomy in Italy. In his time, the Catholic Church relaxed its prohibition against cadaver dissection, in part to allow autopsies in cases of suspicious death. Furthermore, the Italian Renaissance created an environment more friendly to innovative scholarship. Dissection gradually found its way into the training of medical students throughout Europe. It was an unpleasant business, however, and most professors considered it beneath their dignity. In those days before refrigeration or embalming, the odor from the decaying cadaver was unbearable. Dissections were a race against decay. Bleary medical students fought the urge to vomit, lest they incur the wrath of an overbearing professor. Professors typically sat in an elevated chair, the *cathedra*, reading dryly in Latin from Galen or Aristotle while a lower-ranking *barber-surgeon* removed putrefying organs from the cadaver and held them up for the students to see. Barbering and surgery were considered to be “kindred arts of the knife”; today’s barber poles date from this era, their red and white stripes symbolizing blood and bandages.

Vesalius broke with tradition by coming down from the *cathedra* and doing the dissections himself. He was quick to point out that much of the anatomy in Galen’s books was wrong, and he was the first to publish accurate illustrations for teaching anatomy (**fig. 1.1b**). When others began to plagiarize them, Vesalius published the first atlas of anatomy, *De Humani Corporis Fabrica* (*On the Structure of the Human Body*), in 1543. This book began a rich tradition of medical illustration that has been handed down to us through such milestones as *Gray’s Anatomy* (1856) and the vividly illustrated atlases and textbooks of today.

Anatomy preceded physiology and was a necessary foundation for it. What Vesalius was to anatomy, the Englishman **William Harvey** (1578–1657) was to physiology. Harvey is remembered especially for his studies of blood circulation and a little book he published in 1628, known by its abbreviated title *De Motu Cordis* (*On the Motion of the Heart*). He and **Michael Servetus** (1511–53) were the first Western scientists to realize that blood must circulate continuously around the body, from the heart to the other organs and back to the heart again. This flew in the face of Galen’s belief that the liver converted food to blood, the heart pumped blood through the veins to all other organs, and those organs consumed it. Physicians wedded to the ideas of Galen ridiculed Harvey for his theory, though we now know he was correct. Despite persecution and setbacks, Harvey lived to a ripe old age, served as physician to the kings of England, and later did important work in embryology. Most importantly, Harvey’s contributions represent the birth of experimental physiology—the method that generated most of the information in this book.

Modern medicine also owes an enormous debt to those who extended the vision of biologists to the cellular level. In 1609, **Galileo** (1564–1642) patented the compound microscope as a by-product of his work with telescopes. This was essentially a telescope for viewing very tiny objects—a tube with a lens at each end: an *objective lens* near the specimen and an *ocular lens* (eyepiece) near the viewer’s eye, which magnified the first image still further. Galileo never thought, however, to use it on biological material. The first to study cells with a compound microscope was Italian physician–biologist **Marcello Malpighi** (1628–94), who

was among the first to observe blood cells and capillaries as well as capillary blood flow. He published his descriptions in 1661 and is remembered as the father of histology (microscopic anatomy). Englishman **Robert Hooke** (1635–1703), who designed scientific instruments of various kinds, improved the optics, and invented several of the helpful features found in microscopes today—a stage to hold the specimen, an illuminator, and coarse and fine focus controls. His microscopes magnified only about 30 times, but with them, he was the first to see and name cells. In 1663, he observed thin shavings of cork and observed that they “consisted of a great many little boxes,” which he called *cellulae* (little cells) after the cubicles of a monastery (**fig. 1.2**). He later observed living cells “filled with juices.” Hooke became particularly interested in microscopic examination of such material as insects, plant tissues, and animal parts. He published the first comprehensive book of microscopy, *Micrographia*, in 1665.

Antony van Leeuwenhoek (an-TOE-nee vahn LAY-wen-hook) (1632–1723), a Dutch textile merchant, invented a *simple* (single-lens) *microscope*, originally for the purpose of examining the weave of fabrics. His microscope was a beadlike lens

FIGURE 1.2 Hooke’s Compound Microscope. (a) The compound microscope had a lens at each end of a tubular body. (b) Hooke’s drawing of cork cells, showing the thick cell walls characteristic of plants.

a: National Museum of Health and Medicine, Silver Spring, MD; b: Bettmann/Getty Images

mounted in a metal plate equipped with a movable specimen clip. Even though his microscopes were simpler than Hooke's, they achieved much greater useful magnification (up to 200 $\times$) owing to Leeuwenhoek's superior lens-making technique. Out of curiosity, he examined a drop of lake water and was astonished to find a variety of microorganisms—"little animalcules," he called them, "very prettily a-swimming." He went on to observe practically everything he could get his hands on, including blood cells, blood capillaries, sperm, muscular tissue, and bacteria from tooth scrapings. Leeuwenhoek began submitting his observations to the Royal Society of London in 1673. He was praised at first, and his observations were eagerly read by scientists, but enthusiasm for the microscope didn't last. By the end of the seventeenth century, it was treated as a mere toy for the upper classes, as amusing and meaningless as a kaleidoscope. Leeuwenhoek and Hooke had even become the brunt of satire. But probably no one in history had looked at nature in such a revolutionary way. By taking biology to the cellular level, the two men had laid an entirely new foundation for the modern medicine to follow centuries later.

The Hooke and Leeuwenhoek microscopes produced poor images with blurry edges (*spherical aberration*) and rainbow-like distortions (*chromatic aberration*). These problems had to be solved before the microscope could be widely used as a biological tool. In the nineteenth century, German inventors greatly improved the compound microscope, adding the condenser and developing superior optics. With improved microscopes, biologists began eagerly examining a wider variety of specimens. By 1839, botanist **Matthias Schleiden** (1804–81) and zoologist **Theodor Schwann** (1810–82) concluded that all organisms were composed of cells. Although it took another century for this idea to be generally accepted, it became the first tenet of the **cell theory**, added to by later biologists and summarized in chapter 3. The cell theory was perhaps the most important breakthrough in biomedical history; all functions of the body are now interpreted as the effects of cellular activity.

Although the philosophical foundation for modern medicine was largely established by the time of Leeuwenhoek, Hooke, and Harvey, clinical practice was still in a dismal state. Few doctors attended medical school or received any formal education in basic science or human anatomy. Physicians tended to be ignorant, ineffective, and pompous. Their practice was heavily based on expelling imaginary toxins from the body by bleeding their patients or inducing vomiting, sweating, or diarrhea. They performed operations with filthy hands and instruments, spreading lethal infections from one patient to another and refusing, in their vanity, to believe that they themselves were the carriers of disease. Countless women died of infections acquired during childbirth from their obstetricians. Fractured limbs often became gangrenous and had to be amputated, and there was no anesthesia to lessen the pain. Disease was still widely attributed to demons and witches, and many people felt they would be interfering with God's will if they tried to treat it.

1.2c Living in a Revolution

This short history brings us only to the threshold of modern biomedical science; it stops short of such momentous discoveries as

the germ theory of disease, the mechanisms of heredity, and the structure of DNA. In the twentieth century, basic biology and biochemistry yielded a much deeper understanding of how the body works. Advances in medical imaging enhanced our diagnostic ability and life-support strategies. We witnessed monumental developments in chemotherapy, immunization, anesthesia, surgery, organ transplants, and human genetics. By the close of the twentieth century, we had discovered the chemical "base sequence" of every human gene and begun attempting gene therapy to treat children born with diseases recently considered incurable. As future historians look back on our present era, they may exult about the Genetic Revolution in which you are now living.

Several discoveries of the nineteenth and twentieth centuries, and the men and women behind them, are covered in short historical sketches in later chapters. Yet, the stories told in this chapter are different in a significant way. The people discussed here were pioneers in establishing the scientific way of thinking. They helped to replace superstition with an appreciation of natural law. They bridged the chasm between mystery and medication. Without this intellectual revolution, those who followed could not have conceived of the right questions to ask, much less a method for answering them.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

3. In what way did the followers of Galen disregard his advice? How does Galen's advice apply to you and this book?
4. Describe two ways in which Vesalius improved medical education and set standards that remain relevant today.
5. How is our concept of human form and function today affected by inventors from the seventeenth to the nineteenth centuries?

1.3 Scientific Method

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the inductive and hypothetico–deductive methods of obtaining scientific knowledge;
- b. describe some aspects of experimental design that help to ensure objective and reliable results; and
- c. explain what is meant by *hypothesis*, *fact*, *law*, and *theory* in science.

Health is an area littered with probably more pseudoscientific fallacies and frauds than any other. We're called upon constantly to judge which claims are trustworthy and which are bogus; which ones may help, which may kill, and which may benefit no one but scam artists able to talk desperate and credulous people out of their money. To make sound judgments about

FIGURE 1.3 Biomedical Research. Research scientists employ habits of thought we call the scientific method to ensure the objectivity, reliability, and reproducibility of their results and conclusions.

AshTproductions/Shutterstock

them depends on an appreciation of how scientists think, how they set standards for truth, and why their claims are more reliable than others.

When we describe a research method or way of thinking as scientific, we mean it's based on assumptions and methods that yield reliable, objective, testable information about nature (**fig. 1.3**). The assumptions of science are ideas that have proven fruitful in the past—for example, the idea that natural phenomena have natural causes, that nature is predictable and understandable, and that humans are a product of nature and subject to its laws. **Scientific method** is highly variable. It refers not to formulaic observational procedures, but to certain habits of disciplined creativity, careful observation, logical thinking, and honest analysis of one's observations and conclusions. Science cultivates habits of inquiry meant to arrive at truthful representations of nature—objective conclusions that will stand up to efforts to find fault with them. Its conclusions are not infallible, but are always open to correction and refinement when new evidence demands it.

The following brief introduction is meant to give you some insight into the habits of thought that give credibility to scientific claims and underlie the scientific information presented throughout this book.

1.3a The Inductive Method

The **inductive method** is a process of making numerous observations until one feels confident in drawing generalizations and predictions from them. What we know of anatomy is a product of the inductive method. We describe the normal structure of the body based on observations of many bodies.

This raises the issue of what is considered proof in science. We can never prove a claim beyond all possible refutation. We can, however, consider a statement as proven *beyond reasonable doubt*

if it was arrived at by reliable methods of observation, tested and confirmed repeatedly, and not falsified by any credible observation. In science, all truth is tentative; there's no room for dogma. We must always be prepared to abandon yesterday's truth if tomorrow's facts disprove it.

1.3b The Hypothetico–Deductive Method

Most physiological knowledge was obtained by the **hypothetico–deductive method**. An investigator begins by asking a question and formulating a **hypothesis**—an educated speculation or possible answer to the question. A good hypothesis must be (1) consistent with what is already known and (2) capable of being tested and possibly falsified by evidence. **Falsifiability** means that if we claim something is scientifically true, we must be able to specify what evidence it would take to prove it wrong. If nothing could possibly prove it wrong, then it's not scientific.

▶▶▶ APPLY WHAT YOU KNOW

The ancients thought that gods or invisible demons caused epilepsy. Today, epileptic seizures are attributed to bursts of abnormal electrical activity in nerve cells of the brain. Explain why one of these claims is falsifiable (and thus scientific), whereas the other claim is not.

The purpose of a hypothesis is to suggest a method for answering a question. From the hypothesis, a researcher makes a deduction, typically in the form of an “if–then” prediction: *If my hypothesis on epilepsy is correct and I record the brain waves of patients during seizures, then I should observe abnormal bursts of activity.* A properly conducted experiment yields observations that either support a hypothesis or require the scientist to modify or abandon it, formulate a better hypothesis, and test that one. Hypothesis testing operates in cycles of conjecture and disproof until one is found that is supported by the evidence.

1.3c Experimental Design

Doing an experiment properly involves several important considerations. What shall I measure and how can I measure it? What effects should I watch for and which ones should I ignore? How can I be sure my results are due to the variables that I manipulate and not due to something else? When working on human subjects, how can I prevent the subject's expectations or state of mind from influencing the results? How can I eliminate my own biases and be sure that even the most skeptical critics will have as much confidence in my conclusions as I do? Several elements of experimental design address these issues:

- **Sample size.** The number of subjects (animals or people) used in a study is the sample size. An adequate sample size controls for chance events and individual variations in response and thus enables us to place more confidence in the outcome. For example, would you rather trust your health to a drug that was tested on 5 people or one tested on 5,000? Why?

- **Controls.** Biomedical experiments require comparison between treated and untreated individuals so that we can judge whether the treatment has any effect. A **control group** consists of subjects that are as much like the **treatment group** as possible except with respect to the variable being tested. For example, there is evidence that garlic lowers blood cholesterol levels. In one study, volunteers with high cholesterol were each given 800 mg of garlic powder daily for 4 months and exhibited an average 12% reduction in cholesterol. Was this a significant reduction, and was it due to the garlic? It's impossible to say without comparison to a control group of similar people who received no treatment. In this study, the control group averaged only a 3% reduction in cholesterol, so garlic *seems* to have made a difference.
- **Psychosomatic effects.** Psychosomatic effects (effects of the subject's state of mind on his or her physiology) can have an undesirable effect on experimental results if we don't control for them. In drug research, it is therefore customary to give the control group a **placebo** (pla-SEE-bo)—a substance with no significant physiological effect on the body. If we were testing a drug, for example, we could give the treatment group the drug and the control group identical-looking sugar tablets. Neither group must know which tablets it is receiving. If the two groups showed significantly different effects, we could feel confident that it didn't result from a knowledge of what they were taking.
- **Experimenter bias.** In the competitive, high-stakes world of medical research, experimenters may want certain results so much that their biases, even subconscious ones, can affect their interpretation of the data. One way to control for this is the **double-blind method**. In this procedure, neither the subject to whom a treatment is given nor the person giving it and recording the results knows whether that subject is receiving the experimental treatment or the placebo. A researcher may prepare identical-looking tablets, some with the drug and some with placebo; label them with code numbers; and distribute them to participating physicians. The physicians themselves don't know whether they're administering drug or placebo, so they can't give the subjects even accidental hints of which substance they're taking. When the data are collected, the researcher can correlate them with the composition of the tablets and determine whether the drug had more effect than the placebo.
- **Statistical testing.** If you tossed a coin 100 times, you would expect it to come up about 50 heads and 50 tails. If it actually came up 48:52, you would probably attribute this to random error rather than bias in the coin. But what if it came up 40:60? At what point would you begin to suspect bias? This type of problem is faced routinely in research—how great a difference must there be between control and treatment groups before we feel confident that it was due to the treatment and not merely random variation? What if

a treatment group exhibited a 12% reduction in cholesterol level and the placebo group a 10% reduction? Would this be enough to conclude that the treatment was effective? Scientists are well grounded in **statistical tests** that can be applied to the data—the chi-square test, the *t* test, and analysis of variance, for example. A typical outcome of a statistical test may be expressed, “We can be 99.5% sure that the difference between group A and group B was due to the experimental treatment and not to random variation.” Science is grounded not in statements of absolute truth, but in statements of probability.

1.3d Peer Review

When a scientist applies for funds to support a research project or submits results for publication, the application or manuscript is submitted to **peer review**—a critical evaluation by other experts in that field. Even after a report is published, if the results are important or unconventional, other scientists may attempt to reproduce them to see if the author was correct. At every stage from planning to postpublication, scientists are therefore subject to intense scrutiny by their colleagues. Peer review is one mechanism for ensuring honesty, objectivity, and quality in science.

1.3e Facts, Laws, and Theories

The most important product of scientific research is understanding how nature works—whether it be the nature of a pond to an ecologist or the nature of a liver cell to a physiologist. We express our understanding as *facts*, *laws*, and *theories* of nature. It is important to appreciate the differences among these.

A scientific **fact** is information that can be independently verified by any trained person—for example, the fact that an iron deficiency leads to anemia. A **law of nature** is a generalization about the predictable ways in which matter and energy behave. It is the result of inductive reasoning based on repeated, confirmed observations. Some laws are expressed as concise verbal statements, such as the *law of complementary base pairing*: In the double helix of DNA, a chemical base called adenine always pairs with one called thymine, and a base called guanine always pairs with cytosine. Other laws are expressed as mathematical formulae, such as *Boyle's law*, used in respiratory physiology: Under specified conditions, the volume of a gas (*V*) is inversely proportional to its pressure (*P*)—that is,

$$V \propto 1/P.$$

A **theory** is an explanatory statement or set of statements derived from facts, laws, and confirmed hypotheses. Some theories have names, such as the *cell theory*, the *fluid-mosaic theory* of cell membranes, and the *sliding filament theory* of muscle contraction. Most, however, remain unnamed. The purpose of a theory is not only to concisely summarize what we already know but, moreover, to suggest directions for further study and to help predict what the findings should be if the theory is correct.

Law and *theory* mean something different in science than they do to most people. In common usage, a law is a rule created and enforced by people; we must obey it or risk a penalty. A law of nature, however, is a description; laws don't *govern* the universe—they *describe* it. Laypeople tend to use the word *theory* for what a scientist would call a hypothesis—for example, “I have a theory why my car won't start.” The difference in meaning causes significant confusion when it leads people to think that a scientific theory (such as the theory of evolution) is merely a guess or conjecture, instead of recognizing it as a summary of conclusions drawn from a large body of observed facts. The concepts of gravity and electrons are theories, too, but this doesn't mean they're merely speculations.

▶▶▶ APPLY WHAT YOU KNOW

Was the cell theory proposed by Schleiden and Schwann more a product of the hypothetico–deductive method or of the inductive method? Explain your answer.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

6. Describe the general process involved in the inductive method.
7. Describe some sources of potential bias in biomedical research. What are some ways of minimizing such bias?
8. Is there more information in an individual scientific fact or in a theory? Explain.

1.4 Human Origins and Adaptations

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain why evolution is relevant to understanding human form and function;
- b. define *evolution* and *natural selection*;
- c. describe some human characteristics that can be attributed to the tree-dwelling habits of earlier primates; and
- d. describe some human characteristics that evolved later in connection with upright walking.

If any two theories have the broadest implications for understanding the human body, they are probably the *cell theory* and the *theory of natural selection*. No understanding of human form and function is complete without an understanding of our evolutionary history, of how natural selection adapted the body to its ancestral habitat. As an explanation of how species originate and change through time, natural selection was the brainchild of **Charles Darwin** (1809–82)—certainly the most influential biologist who ever lived. His book, *On the Origin of*

Species by Means of Natural Selection (1859), has been called “the book that shook the world.” In presenting the first well-supported theory of how evolution works, it not only caused the restructuring of all of biology but also profoundly changed the prevailing view of our origin, nature, and place in the universe. In *The Descent of Man* (1871), Darwin directly addressed the issue of human evolution and emphasized features of anatomy and behavior that reveal our relationship to other animals. Here we will touch just briefly on how natural selection helps explain some of the distinctive characteristics seen today in our species, *Homo sapiens*.

1.4a Evolution, Selection, and Adaptation

Evolution simply means change in the genetic composition of a population of organisms. Examples include the evolution of bacterial resistance to antibiotics, the appearance of new strains of the flu virus, and the emergence of new species of organisms.

Evolution works largely through the principle of **natural selection**, which states essentially this: Some individuals within a species have hereditary advantages over their competitors—for example, better camouflage, disease resistance, or ability to attract mates—that enable them to produce more offspring. They pass these advantages on to their offspring, and such characteristics therefore become more and more common in successive generations. This brings about the genetic change in a population that constitutes evolution.

Natural forces that promote the reproductive success of some individuals more than others are called **selection pressures**. They include such things as climate, predators, disease, competition, and food. **Adaptations** are features of anatomy, physiology, and behavior that evolve in response to these selection pressures and enable an organism to cope with the challenges of its environment.

Darwin could scarcely have predicted the overwhelming mass of genetic, molecular, fossil, and other evidence of human evolution that would accumulate in the twentieth century and further substantiate his theory. Modern methods in molecular genetics, for example, reveal less difference between the DNA of chimpanzees and humans than there is between chimpanzees and gorillas. That is, a chimpanzee's closest living relative is not the gorilla—it is us, *Homo sapiens*.

Several aspects of our anatomy make little sense without an awareness that the human body has a history (see Deeper Insight 1.1). Our evolutionary relationship to other species is also important in choosing animals for biomedical research. If there were no issues of cost, availability, or ethics, we might test drugs on our close living relatives, the chimpanzees, before approving them for human use. Their genetics, anatomy, and physiology are most similar to ours, and their reactions to drugs therefore afford the best prediction of how the human body would react. On the other hand, if we had no kinship with any other species, the selection of a test species would be arbitrary; we might as well use frogs or snails. In reality, we compromise. Rats and mice are used extensively for research because they are fellow mammals with a physiology similar to ours, but they present fewer of the

DEEPER INSIGHT 1.1

EVOLUTIONARY MEDICINE

Vestiges of Human Evolution

One of the classic lines of evidence for evolution, debated even before Darwin was born, is **vestigial organs**. These structures are the remnants of organs that apparently were better developed and more functional in the ancestors of a species. They now serve little or no purpose or, in some cases, have been converted to new functions.

Our bodies, for example, are covered with millions of hairs, each equipped with a useless little *arrector muscle*. In other mammals, these muscles fluff the hair and conserve heat. In humans, they merely produce goose bumps. Above each ear, we have three *auricularis muscles*. In other mammals, they move the ears to receive sounds better or to flick off flies and other pests, but most people can't contract them at all. As Darwin said, it makes no sense that humans would have such structures were it not for the fact that we came from ancestors in which they were functional.

aforementioned issues than chimpanzees or other mammals do. An animal species or strain selected for research on a particular problem is called a **model**—for example, a mouse model for acute lymphocytic leukemia.

1.4b Our Basic Primate Adaptations

We belong to an order of mammals called the Primates, which also includes the monkeys and apes. Some of our anatomical and physiological features can be traced to the earliest primates, which descended from certain squirrel-size, insect-eating, African mammals that took up life in the trees 55 to 60 million years ago. This **arboreal**⁹ (treetop) habitat probably afforded greater safety from predators, less competition, and a rich food supply of leaves, fruit, insects, and lizards. But the forest canopy is a challenging world, with dim and dappled sunlight, swaying branches, shifting shadows, and prey darting about in the dense foliage. Any new feature that enabled arboreal animals to move about more easily in the treetops would have been strongly favored by natural selection. Thus, the shoulder became more mobile and enabled primates to reach out in any direction (even overhead, which few other mammals can do). The thumbs became fully **opposable**—they could cross the palm to touch the fingertips—and enabled primates to hold small objects and manipulate them more precisely than other mammals could. Opposable thumbs made the hands **prehensile**¹⁰—able to grasp objects by encircling them with the thumb and fingers (**fig. 1.4**). The thumb is so important that it receives highest priority in the repair of hand injuries. If the thumb can be saved, the hand can be reasonably functional; if it is lost, hand functions are severely diminished.

⁹arboreal = tree; eal = pertaining to

¹⁰prehensile = to seize

FIGURE 1.4 Human Adaptations Shared with Other Primates. Some major aspects of primate evolution are the opposable thumb, prehensile hand, forward-facing eyes, and stereoscopic vision. In humans, the hand became refined for increasingly sophisticated manipulation of objects.

Chimpanzee: Tim Davis/Science Source

The eyes of primates moved to a more forward-facing position, which allowed for **stereoscopic**¹¹ vision (depth perception). This adaptation provided better hand–eye coordination in catching and manipulating prey, with the added advantage of making it easier to judge distances accurately in leaping from tree to tree. Color vision, rare among mammals, is also a primate hallmark. Primates eat mainly fruit and leaves. The ability to distinguish subtle shades of orange and red enables them to distinguish ripe, sugary fruits from unripe ones. Distinguishing subtle shades of green helps them to differentiate between tender young leaves and tough, more toxic older foliage.

Various fruits ripen at different times and in widely separated places in the tropical forest. This requires a good memory of what will be available, when, and how to get there. Larger brains might have evolved in response to the challenge of efficient food finding and, in turn, laid the foundation for more sophisticated social organization.

¹¹stereo = solid; scop = vision

None of this is meant to imply that humans evolved from monkeys—a common misconception about evolution that no biologist believes. Monkeys, apes, and humans do, however, share common ancestors. Our relationship is not like parent and child, but more like cousins who have the same grandparents. Observations of monkeys and apes provide insight into how primates adapt to the arboreal habitat and therefore how certain human adaptations probably originated.

1.4c Walking Upright

About 4 to 5 million years ago, parts of Africa became hotter and drier, and much of the forest was replaced by savanna (grassland). Some primates adapted to living on the savanna, but this was a dangerous place with more predators and less protection. Just as squirrels and monkeys stand briefly on their hind legs to look around for danger, so would these early ground dwellers. Being able to stand up not only helps an animal stay alert, but also frees the forelimbs for purposes other than walking. Chimpanzees sometimes walk upright to carry food, infants, or weapons (sticks and rocks), and it is reasonable to suppose that our early ancestors did so too.

These advantages are so great that they favored skeletal modifications that made **bipedalism**¹²—standing and walking on two legs—easier. Fossil evidence indicates that bipedalism was firmly established more than 4 million years ago. The anatomy of the human pelvis, femur, knee, great toe, foot arches, spinal column, skull, arms, and many muscles became adapted for bipedal locomotion (see Deeper Insight 8.5), as did many aspects of human family life and society. As the skeleton and muscles became adapted for bipedalism, brain volume increased dramatically, from 400 mL around 4 million years ago to an average of 1,350 mL today. It must have become increasingly difficult for a fully developed, large-brained infant to pass through the mother's pelvic outlet at birth. This may explain why humans are born in a relatively immature, helpless state compared with other mammals, before their nervous systems have matured and the bones of the skull have fused. The helplessness of human young and their extended dependence on parental care may help to explain why humans have such exceptionally strong family ties.

Most of the oldest bipedal primates are classified in the genus *Australopithecus* (aus-TRAL-oh-PITH-eh-cus). About 2.5 million years ago, hominids appeared with taller stature, greater brain volumes, simple stone tools, and probably articulate speech. These are the earliest members of the genus *Homo*. By at least 1.8 million years ago, *Homo erectus* migrated from Africa to parts of Asia. Anatomically modern *Homo sapiens*, our own species, originated in Africa about 200,000 years ago and is the only surviving hominid species.

This brief account barely begins to explain how human anatomy, physiology, and behavior have been shaped by ancient selection pressures. Later chapters further demonstrate that the evolutionary perspective provides a meaningful understanding of why humans are the way we are. Evolution is the basis for

comparative anatomy and physiology, which have been so fruitful for the understanding of human biology. If we weren't related to any other species, those sciences would be pointless.

The emerging science of **evolutionary medicine** analyzes how human disease and dysfunctions can be traced to differences between the artificial environment in which we now live, and the prehistoric environment to which *Homo sapiens* was biologically adapted. For example, we can relate sleep and mood disorders to artificial lighting and night-shift work, and the rise of asthma to our modern obsession with sanitation. Other examples in this book will relate evolution to obesity, diabetes, low-back pain, skin cancer, and other health issues.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

9. Define *adaptation* and *selection pressure*. Why are these concepts important in understanding human anatomy and physiology?
10. Select any two human characteristics and explain how they might have originated in primate adaptations to an arboreal habitat.
11. Select two other human characteristics and explain how they might have resulted from later adaptation to a grassland habitat.

1.5 Human Structure

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. list the levels of human structure from the most complex to the simplest;
- b. discuss the value of both reductionistic and holistic viewpoints to understanding human form and function; and
- c. discuss the clinical significance of anatomical variation among humans.

Earlier in this chapter, we observed that human anatomy is studied by a variety of techniques—dissection, palpation, and so forth. In addition, anatomy is studied at several levels of detail, from the whole body down to the molecular level.

1.5a The Hierarchy of Complexity

Consider for the moment an analogy to human structure: The English language, like the human body, is very complex, yet an endless variety of ideas can be conveyed with a limited number of words. All words in English are, in turn, composed of various combinations of just 26 letters. Between an essay and an alphabet are successively simpler levels of organization: paragraphs, sentences, words, and syllables. We can say that language exhibits a

¹²bi = two; ped = foot

FIGURE 1.5 The Body's Structural Hierarchy.

hierarchy of complexity, with letters, syllables, words, and so forth being successive levels of the hierarchy. Humans have an analogous hierarchy of complexity, as follows (**fig. 1.5**):

The organism is composed of organ systems,
 organ systems are composed of organs,
 organs are composed of tissues,
 tissues are composed of cells,
 cells are composed partly of organelles,
 organelles are composed of molecules, and
 molecules are composed of atoms.

The **organism** is a single, complete individual.

An **organ system** is a group of organs with a unique collective function, such as circulation, respiration, or digestion. The human body has 11 organ systems, illustrated in atlas A immediately following this chapter: the integumentary, skeletal, muscular, nervous, endocrine, circulatory, lymphatic, respiratory, urinary, digestive, and reproductive systems. Usually, the organs of one system are physically interconnected, such as the kidneys, ureters, urinary bladder, and urethra, which compose the urinary system.

Beginning with chapter 6, this book is organized around the organ systems.

An **organ** is a structure composed of two or more tissue types that work together to carry out a particular function. Organs have definite anatomical boundaries and are visibly distinguishable from adjacent structures. Most organs and higher levels of structure are within the domain of gross anatomy. However, there are organs within organs—the large organs visible to the naked eye often contain smaller organs visible only with the microscope. The skin, for example, is the body's largest organ. Included within it are thousands of smaller organs: Each hair, nail, gland, nerve, and blood vessel of the skin is an organ in itself. A single organ can belong to two organ systems. For example, the pancreas belongs to both the endocrine and digestive systems.

A **tissue** is a mass of similar cells and cell products that forms a discrete region of an organ and performs a specific function. The body is composed of only four primary classes of tissue: epithelial, connective, nervous, and muscular tissue. Histology, the study of tissues, is the subject of chapter 5.

Cells are the smallest units of an organism that carry out all the basic functions of life; nothing simpler than a cell is considered alive. A cell is enclosed in a *plasma membrane* composed of lipids and proteins. Most cells have one nucleus, an organelle that contains its DNA. *Cytology*, the study of cells and organelles, is the subject of chapters 3 and 4.

Organelles¹³ are microscopic structures in a cell that carry out its individual functions. Examples include mitochondria, centrioles, and lysosomes.

Organelles and other cellular components are composed of **molecules**. The largest molecules, such as proteins, fats, and DNA, are called *macromolecules*. A molecule is a particle composed of at least two **atoms**, which are the smallest particles with unique chemical identities.

The theory that a large, complex system such as the human body can be understood by studying its simpler components is called **reductionism**. First espoused by Aristotle, this has proved to be a highly productive approach; indeed, it is essential to scientific thinking. Yet the reductionistic view is not the only way of understanding human life. Just as it would be very difficult to predict the workings of an automobile transmission merely by looking at a pile of its disassembled gears and levers, one could never predict the human personality from a complete knowledge of the circuitry of the brain or the genetic sequence of DNA. **Holism**¹⁴ is the complementary theory that there are “emergent properties” of the whole organism that can't be predicted from the properties of its separate parts—human beings are more than the sum of their parts. To be most effective, a health-care provider treats not merely a disease or an organ system, but a whole person. A patient's perceptions, emotional responses to life, and confidence in the nurse, therapist, or physician profoundly affect the outcome of treatment. In fact, these psychological factors often play a greater role in a patient's recovery than the physical treatments administered.

¹³*elle* = little

¹⁴*holo* = whole, entire

1.5b Anatomical Variation

A quick look around any classroom is enough to show that no two humans are exactly alike; on close inspection, even identical twins exhibit differences. Yet anatomy atlases and textbooks can easily give the impression that everyone's internal anatomy is the same. This simply is not true. Books such as this one can teach you only the most common structure—the anatomy seen in about 70% or more of people. Someone who thinks that all human bodies are the same internally would make a very confused medical student or an incompetent surgeon.

Some people lack certain organs. For example, most of us have a *palmaris longus* muscle in the forearm and a *plantaris* muscle in the leg, but these are absent from others. Most people have 24 ribs, but as many as 6% of us have 23, 26, or more. Most of us have one spleen and two kidneys, but some have two spleens or only one kidney. Most kidneys are supplied by a single *renal artery* and are drained by one *ureter*, but some have two renal arteries or ureters (*duplex ureters*). Variations in sexual anatomy, physiology, and genetics reveal that not everyone can be simply classified as male or female (see the further discussion in chapter 27). **Figure 1.6** shows some common variations in human anatomy, and Deeper Insight 1.2 describes a particularly dramatic and clinically important variation.

▶▶▶ APPLY WHAT YOU KNOW

People who are allergic to aspirin or penicillin often wear MedicAlert bracelets or necklaces that note this fact in case they need emergency medical treatment and are unable to communicate. Why would it be important for a person with *situs inversus* (see Deeper Insight 1.2) to have this noted on a MedicAlert bracelet?

FIGURE 1.6 Variation in Anatomy of the Kidneys and the Major Arteries Near the Heart.

DEEPER INSIGHT 1.2

CLINICAL APPLICATION

Situs Inversus and Other Unusual Anatomy

In most people, the spleen, pancreas, sigmoid colon, and most of the heart are on the left, whereas the appendix, gallbladder, and most of the liver are on the right. The normal arrangement of these and other internal organs is called *situs solitus* (SITE-us SOL-ih-tus). About 1 in 8,000 people, however, is born with an abnormality called *situs inversus*—the organs of the thoracic and abdominal cavities are reversed between right and left. A selective right–left reversal of the heart is called *dextrocardia*. In *situs perversus*, a single organ occupies an atypical position—for example, a kidney located low in the pelvic cavity instead of high in the abdominal cavity.

Conditions such as dextrocardia in the absence of complete situs inversus can cause serious medical problems. Complete situs inversus, however, usually causes no functional problems because all of the viscera, though reversed, maintain their normal relationships to one another. Situs inversus is often discovered in the fetus by sonography, but many people remain unaware of their condition for decades until it is discovered by medical imaging, on physical examination, or in surgery. You can easily imagine the importance of such conditions in diagnosing appendicitis, performing gallbladder surgery, interpreting an X-ray, auscultating the heart valves, or recording an electrocardiogram.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

12. In the hierarchy of human structure, what is the level between organ system and tissue? Between cell and molecule?
13. How are tissues relevant to the definition of an organ?
14. Why is reductionism a necessary but not sufficient point of view for fully understanding a patient's illness?
15. Why should medical students observe multiple cadavers and not be satisfied to dissect only one?

1.6 Human Function

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. state the characteristics that distinguish living organisms from nonliving objects;
- b. explain the importance of physiological variation among persons;
- c. define *homeostasis* and explain why this concept is central to physiology;
- d. define *negative feedback*, give an example of it, and explain its importance to homeostasis;
- e. define *positive feedback* and give examples of its beneficial and harmful effects; and
- f. define *gradient*, describe the variety of gradients in human physiology, and identify some forms of matter and energy that flow down gradients.

1.6a Characteristics of Life

Why do we consider a growing child to be alive, but not a growing crystal? Is abortion the taking of a human life? If so, what about a contraceptive foam that kills only sperm? As a patient is dying, at what point does it become ethical to disconnect life-support equipment and remove organs for donation? If these organs are alive, as they must be to serve someone else, then why isn't the donor considered alive? Such questions have no easy answers, but they demand a concept of what life is—a concept that may differ with one's biological, medical, legal, ethical, or religious perspective.

Simply put, there is no solid definition of *life*. Defining *life* is elusive, like trying to define *jazz* or *poetry*. We can only list some universal characteristics of things that most people consider to be alive:

- **Organization.** Living things exhibit a far higher level of organization than the nonliving world around them. They

expend a great deal of energy to maintain order, and a breakdown in this order is accompanied by disease and often death.

- **Cellular composition.** Living matter is always compartmentalized into one or more cells.
- **Metabolism.** Living things take in molecules from the environment and chemically change them into molecules that form their own structures, control their physiology, or provide them with energy. **Metabolism**¹⁵ is the sum of all this internal chemical change. There is a constant turnover of molecules in the body. Although you sense a continuity of personality and experience from your childhood to the present, nearly every molecule of your body has been replaced within the past year.
- **Responsiveness and movement.** The ability to sense and react to **stimuli** (changes in the environment) is called *responsiveness* or *excitability*. It occurs at all levels from the single cell to the entire body, and it characterizes all living things from bacteria to you. Responsiveness is especially obvious in animals because of nerve and muscle cells that exhibit high sensitivity to environmental stimuli, rapid transmission of information, and quick reactions. Most living organisms are capable of self-propelled movement from place to place, and all organisms and cells are at least capable of moving substances internally, such as moving food along the digestive tract or moving molecules and organelles from place to place within a cell.
- **Homeostasis.** Although the environment around an organism changes, the individual maintains relatively stable internal conditions—for example, a stable temperature, blood pressure, and body weight. This ability to maintain internal stability, called *homeostasis*, is explored in section 1.6c.
- **Growth and development.** Development is any change in form or function over the lifetime of the organism. In most organisms, it involves two major processes: (1) **differentiation**, the transformation of cells with no specialized function into cells that are committed to a particular task; and (2) growth, an increase in size. Some nonliving things grow, but not in the way your body does. If you let a saturated sugar solution evaporate, crystals grow from it, but not through a change in the composition of the sugar. They merely add more sugar molecules from the solution to the crystal surface. The growth of the body, by contrast, occurs through chemical change (metabolism); for the most part, your body is not composed of the molecules you ate but of molecules made by chemically altering your nutrients.

¹⁵*metabol* = change; *ism* = process

- **Reproduction.** Living organisms produce copies of themselves, thus passing their genes on to new, younger containers—their offspring.
- **Evolution.** All living species exhibit genetic change from generation to generation and therefore evolve. This occurs because *mutations* (changes in DNA structure) are inevitable and environmental selection pressures favor the transmission of some genes more than others. Unlike the other characteristics of life, evolution is a characteristic seen only in the population or gene pool as a whole. No single individual evolves over the course of its life.

Clinical and legal criteria of life differ from these biological criteria. A person who has shown no brain waves for 24 hours, and has no reflexes, respiration, or blood flow other than what is provided by artificial life support, can be declared legally dead. At such time, however, most of the body is still biologically alive and its organs may be useful for transplant.

1.6b Physiological Variation

Earlier we considered the clinical importance of variations in human anatomy, but physiology is even more variable. Physiological variables differ with sex, age, weight, diet, degree of physical activity, genetics, and environment, among other factors. Failure to consider such variation leads to medical mistakes such as overmedication of the elderly or medicating women on the basis of research done on young men. If a textbook states a typical human heart rate, blood pressure, red blood cell count, or body temperature, it is generally assumed, unless otherwise stated, that such values refer to a healthy 22-year-old weighing 58 kg (128 lb) for a female and 70 kg (154 lb) for a male, and a lifestyle of light physical activity and moderate caloric intake (2,000 and 2,800 kcal/day, respectively).

1.6c Negative Feedback and Homeostasis

The human body has a remarkable capacity for self-restoration. Hippocrates commented that it usually returns to a state of equilibrium by itself, and people recover from most illnesses even without the help of a physician. This tendency results from **homeostasis**¹⁶ (HO-me-oh-STAY-sis), the body's ability to detect change, activate mechanisms that oppose it, and thereby maintain relatively stable internal conditions, even in spite of greater changes in the surrounding environment.

French physiologist **Claude Bernard** (1813–78) observed that the internal conditions of the body remain quite constant even when external conditions vary greatly. For example, whether it is freezing cold or swelteringly hot outdoors, the internal temperature of the body stays within a range of about 36° to 37°C (97°–99°F). American physiologist **Walter Cannon** (1871–1945) coined the

term *homeostasis* for this internal stability. This has been one of the most enlightening theories in physiology. We now see physiology as largely a group of mechanisms for maintaining homeostasis, and the loss of homeostatic control as the cause of illness and death. Pathophysiology is essentially the study of unstable conditions that result when our homeostatic controls go awry.

Do not, however, overestimate the degree of internal stability. Internal conditions aren't absolutely constant but fluctuate within a limited range, such as the range of body temperatures noted earlier. The internal state of the body is best described as a **dynamic equilibrium** (balanced change), in which there is a certain **set point** or average value for a given variable (such as 37°C for body temperature) and conditions fluctuate slightly around this point.

The fundamental mechanism that keeps a variable close to its set point is **negative feedback**—a process in which the body senses a change and activates mechanisms that negate or reverse it. By maintaining stability, negative feedback is the key mechanism for maintaining health.

These principles can be understood by comparison to a home heating system (**fig. 1.7a**). Suppose it is a cold winter day and you have set your thermostat for 20°C (68°F)—the set point. If the room becomes too cold, a temperature-sensitive switch in the thermostat turns on the furnace. The temperature rises to slightly above the set point, then the switch breaks the circuit and turns off the furnace. This is a negative feedback process that reverses the falling temperature and keeps it within a narrow range of the set point. When the furnace turns off, the temperature slowly drops again until the switch is reactivated—thus, the furnace cycles on and off all day. The room temperature doesn't stay at exactly 20°C but fluctuates slightly—the system maintains a state of dynamic equilibrium in which the temperature averages 20°C and deviates only slightly from the set point. Because feedback mechanisms alter the original changes that triggered them (temperature, for example), they are often called **feedback loops**.

Body temperature is similarly regulated by a “thermostat”—a group of nerve cells in the base of the brain that monitor the temperature of the blood. If you become overheated, the thermostat triggers heat-losing mechanisms (**fig. 1.7b**). One of these is **vasodilation** (VAY-zo-dy-LAY-shun), the widening of blood vessels. When vessels of the skin dilate, warm blood flows closer to the body surface and loses heat to the surrounding air. If this isn't enough to return your temperature to normal, sweating occurs; the evaporation of water from the skin has a powerful cooling effect (see Deeper Insight 1.3). Conversely, if it is cold outside and your body temperature drops much below 37°C, these nerve cells activate heat-conserving mechanisms. The first to be activated is **vasoconstriction**, a narrowing of the blood vessels in the skin, which serves to retain warm blood deeper in your body and reduce heat loss. If this isn't enough, the brain activates shivering—muscle tremors that generate heat.

Let's consider one more example—homeostatic control of blood pressure. When you first rise from bed in the morning, gravity causes some of your blood to drain away from your head and upper torso, resulting in falling blood pressure in this region—a

¹⁶homeo = the same; stas = to place, stand, stay

FIGURE 1.7 Negative Feedback in Thermoregulation.

(a) The negative feedback loop that maintains room temperature. (b) Negative feedback usually keeps the human body temperature within about 0.5°C of a 37°C set point. Cutaneous vasoconstriction and shivering set in when the body temperature falls too low, and soon raise it. Cutaneous vasodilation and sweating set in when body temperature rises too high, and soon lower it.

? How does vasodilation reduce the body temperature?

local imbalance in homeostasis (**fig. 1.8**). This is detected by sensory nerve endings called *baroreceptors* in large arteries above the heart. They transmit nerve signals to the brainstem, where we have a *cardiac center* that regulates the heart rate. The cardiac center responds by transmitting nerve signals to the heart, which speed it up. The faster heart rate quickly raises the blood pressure and restores normal homeostasis. In elderly people, this feedback loop is sometimes slow to respond, and they may feel dizzy as they rise from a reclining position and their cerebral blood pressure falls. This sometimes causes fainting.

DEEPER INSIGHT 1.3 MEDICAL HISTORY

Men in the Oven

English physician Charles Blagden (1748–1820) staged a rather theatrical demonstration of homeostasis long before Cannon coined the word. In 1775, Blagden spent 45 minutes in a chamber heated to 127°C (260°F)—along with a dog, beefsteaks and eggs, and some research associates. Being dead and unable to maintain homeostasis, the steaks were cooked well done in as little as 13 minutes and almost dry in 47 minutes, and the eggs were cooked hard. But being alive and capable of evaporative cooling, the dog panted and the men sweated profusely. Even at such extreme room temperatures, the men's oral temperatures were only 37° to 38°C (98°–100°F). Blagden said their nostrils felt scorched each time they inhaled the hot room air, and cooled each time they exhaled. Everyone including the dog survived, but history does not record whether the men ate the steak in celebration or shared it with the dog.

This reflexive correction of blood pressure (*baroreflex*) illustrates three common, although not universal, components of a feedback loop: a receptor, an integrating center, and an effector. The **receptor** is a structure that senses a change in the body, such as the stretch receptors that monitor blood pressure. The **integrating (control) center**, such as the cardiac center of the

FIGURE 1.8 Homeostatic Compensation for a Postural Change in Blood Pressure.

brain, is a mechanism that processes this information, relates it to other available information (for example, comparing what the blood pressure is with what it should be), and makes a decision about what the appropriate response should be. The **effector** is the cell or organ that carries out the final corrective action. In the foregoing example, it is the heart. The response, such as the restoration of normal blood pressure, is then sensed by the receptor, and the feedback loop is complete.

1.6d Positive Feedback and Rapid Change

Positive feedback is a self-amplifying cycle in which a physiological change leads to even greater change in the same direction, rather than producing the corrective effects of negative feedback. Positive feedback is often a normal way of producing rapid change. When a woman is giving birth, for example, the head of the fetus pushes against her cervix (the neck of the uterus) and stimulates its nerve endings (**fig. 1.9**). Nerve signals travel to the brain, which, in turn, stimulates the pituitary gland to secrete the hormone oxytocin. Oxytocin travels in the blood and stimulates the uterus to contract. This pushes the

fetus downward, stimulating the cervix still more and causing the positive feedback loop to be repeated. Labor contractions therefore become more and more intense until the fetus is expelled. Other cases of beneficial positive feedback are seen later in this book in, for example, blood clotting, protein digestion, and the generation of nerve signals.

Frequently, however, positive feedback is a harmful or even life-threatening process. This is because its self-amplifying nature can quickly change the internal state of the body to something far from its homeostatic set point. Consider a high fever, for example. A fever triggered by infection is beneficial up to a point, but if the body temperature rises much above 40°C (104°F), it can create a dangerous positive feedback loop. This high temperature raises the metabolic rate, which makes the body produce heat faster than it can get rid of it. Thus, temperature rises still further, increasing the metabolic rate and heat production still more. This “vicious circle” becomes fatal at approximately 45°C (113°F). Thus, positive feedback loops often create dangerously out-of-control situations that require emergency medical treatment.

1.6e Gradients and Flow

Another fundamental concept that will arise repeatedly in this book is that matter and energy tend to *flow down gradients*. This simple principle underlies processes as diverse as blood circulation, respiratory airflow, urine formation, nutrient absorption, body water distribution, temperature regulation, and the action of nerves and muscles.

A physiological **gradient** is a difference in chemical concentration, electrical charge, physical pressure, temperature, or other variable between one point and another. If matter or energy moves from the point where this variable has a higher value to the point with a lower value, we say it flows **down the gradient**—for example, from a warmer to a cooler point, or a place of high chemical concentration to one of lower concentration. Movement in the opposite direction is **up the gradient**.

Outside of biology, *gradient* can mean a hill or slope, and this affords us a useful analogy to biological processes (**fig. 1.10a**). A wagon released at the top of a hill will roll down it (“flow”) spontaneously, without need for anyone to exert energy to move it. Similarly, matter and energy in the body spontaneously flow down gradients, without the expenditure of metabolic energy. Movement up a gradient does require an energy expenditure, just as we would have to push or pull a wagon to move it uphill.

Consider some examples and analogies. If you open a water tap with a garden hose on it, you create a **pressure gradient**; water flows down the hose from the high-pressure point at the tap to the low-pressure point at the open end. Each heartbeat is like that, creating a gradient from high blood pressure near the heart to low pressure farther away; blood flows down this gradient away from the heart (**fig. 1.10b**). When we inhale, air flows down a pressure gradient from the surrounding atmosphere to pulmonary air passages where the pressure is lower. A pressure gradient

FIGURE 1.9 Positive Feedback in Childbirth.

? Could childbirth as a whole be considered a negative feedback event? Discuss.

FIGURE 1.10 Flow Down Gradients. (a) A wagon rolling downhill (down a gradient) (left) is a useful analogy to spontaneous, gradient-driven physiological processes. Moving up a gradient (right) requires an energy input. (b) Blood flowing down a pressure gradient. (c) Dietary sugars flowing down a concentration gradient into an intestinal cell. (d) Sodium ions flowing down an electrical gradient into a cell. (e) Heat flowing down a thermal gradient to leave the body through the skin.

also drives the process in which the kidneys filter water and waste products from the blood.

Chemicals flow down **concentration gradients**. When we digest starch, a high concentration of sugars accumulates in the small intestine. The cells lining the intestine contain only a low concentration of sugars, so sugars flow from the intestinal space into these cells, thus becoming absorbed into the body's tissues (**fig. 1.10c**). Water flows through cell membranes and epithelia by *osmosis*, from the side where it is more concentrated to the side where it is less so.

Charged particles flow down **electrical gradients**. Suppose there is a high concentration of sodium ions (Na^+) just outside a cell and much lower concentration inside, so the outer surface of the cell membrane has a relatively positive charge and the inner surface is relatively negative (**fig. 1.10d**). If we open channels in the membrane that will let sodium pass, sodium ions rush into the cell, flowing down their electrical gradient. Because each Na^+ carries a positive charge, this flow constitutes an electrical current through the membrane. We tap this current to make our nerves fire, our heart beat, and our muscles contract. In many cases, the flow of ions is governed by a combination of concentration and electrical charge differences between two points, and we say that ions flow down **electrochemical gradients**. These will be studied especially in connection with muscle and nerve action in chapters 11 and 12.

Heat flows down a **thermal gradient**. Suppose there is warm blood flowing through small arteries close to the skin surface, and the air temperature around the body is cooler (**fig. 1.10e**). Heat will flow from the blood through the tissues and to the surrounding air, down its thermal gradient, and be lost from the body. You will see in chapter 27 that heat flow is also important in preventing the testes from overheating, which would otherwise prevent sperm production.

Thus, you can see there are many applications in human physiology for this universal tendency of matter and energy to flow down gradients. This principle arises many times in the chapters to follow.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

16. List four biological criteria of life and one clinical criterion. Explain how a person could be clinically dead but biologically alive.
17. What is meant by *dynamic equilibrium*? Why would it be wrong to say homeostasis prevents internal change?
18. Explain why stabilizing mechanisms are called *negative feedback*.
19. Explain why positive feedback is more likely than negative feedback to disturb homeostasis.
20. Active tissues generate carbon dioxide, which diffuses out of the tissue into the bloodstream, to be carried away. Is this diffusion into the blood a case of flow up a gradient or down? Explain.

1.7 The Language of Medicine

Expected Learning Outcomes

When you have completed this section, you should be able to

- explain why modern anatomical terminology is so heavily based on Greek and Latin;
- recognize eponyms when you see them;
- describe the efforts to achieve an internationally uniform anatomical terminology;
- break medical terms down into their basic word elements;
- state some reasons why the literal meaning of a word may not lend insight into its definition;
- relate singular noun forms to their plural and adjective forms; and
- discuss why precise spelling is important in anatomy and physiology.

One of the greatest challenges faced by students of anatomy and physiology is the vocabulary. In this book, you will encounter such Latin terms as *corpus callosum* (a brain structure), *ligamentum arteriosum* (a small fibrous band near the heart), and *extensor carpi radialis longus* (a forearm muscle). You may wonder why structures aren't named in "just plain English," and how you will ever remember such formidable names. This section will give you some answers to these questions and some useful tips on mastering anatomical terminology.

1.7a The History of Anatomical Terminology

The major features of human gross anatomy have standard international names prescribed by a book titled the *Terminologia Anatomica* (TA). The TA was codified in 1998 by an international committee of anatomists and approved by professional associations of anatomists in more than 50 countries.

About 90% of today's medical terms are formed from just 1,200 Greek and Latin roots. Why those two languages? Scientific investigation began in ancient Greece and soon spread to Rome. The Greeks and Romans coined many of the words still used in human anatomy today: *duodenum*, *uterus*, *prostate*, *cerebellum*, *diaphragm*, *sacrum*, *amnion*, and others. In the Renaissance, the fast pace of discovery required a profusion of new terms to describe things. Anatomists in different countries began giving different names to the same structures. Adding to the confusion, they often named new structures and diseases in honor of their esteemed teachers and predecessors, giving us such nondescriptive terms as *fallopian tube* and *duct of Santorini*. Terms coined from the names of people, called **eponyms**,¹⁷ afford little clue as to what a structure or condition is.

In hopes of resolving this growing confusion, anatomists began meeting as early as 1895 to devise a uniform international

terminology. After several false starts, they agreed on a list of terms that rejected all eponyms and gave each structure a unique Latin name to be used worldwide. Even if you were to look at an anatomy atlas in Korean or Arabic, the illustrations may be labeled with the same Latin terms as in an English-language atlas. That list served for many decades until recently replaced by the TA, which prescribes both Latin names and accepted English equivalents. The terminology in this book conforms to the TA except where undue confusion would result from abandoning widely used, yet unofficial, terms.

1.7b Analyzing Medical Terms

The task of learning medical terminology seems overwhelming at first, but it is a simple skill to become more comfortable with the technical language of medicine. People who find scientific terms confusing and difficult to pronounce, spell, and remember often feel more confident once they realize the logic of how terms are composed. A term such as *hyponatremia* is less forbidding once we recognize that it is composed of three common word elements: *hypo-* (below normal), *natr-* (sodium), and *-emia* (blood condition). Thus, hyponatremia is a deficiency of sodium in the blood. Those word elements appear over and over in many other medical terms: *hypothermia*, *natriuretic*, *anemia*, and so on. Once you learn the meanings of *hypo-*, *natri-*, and *-emia*, you already have the tools to at least partially understand hundreds of other biomedical terms. In appendix E, you will find a lexicon of word elements commonly footnoted in this book.

Scientific terms are typically composed of one or more of the following elements:

- At least one *root* (*stem*) that bears the core meaning of the word. In *cardiology*, for example, the root is *cardi-* (heart). Many words have two or more roots. In *cardiomyopathy*, for example, the roots are *cardi-* (heart), *my-* (muscle), and *path-* (disease).
- Combining vowels* that are often inserted to join roots and make the word easier to pronounce. In *cardiomyopathy*, each *o* is a combining vowel. Although *o* is the most common combining vowel, all vowels of the alphabet are used in this way, such as *a* in *ligament*, *e* in *vitreous*, *i* in *fusiform*, *u* in *ovulation*, and *y* in *tachycardia*. Some words, such as *intervertebral*, have no combining vowels. A combination of a root and combining vowel is called a *combining form*; for example, *chrom-* (color) + *o* (a combining vowel) make the combining form *chromo-*, as in *chromosome*.
- A *prefix* may be present to modify the core meaning of the word. For example, *gastric* (pertaining to the stomach or to the belly of a muscle) takes on a variety of new meanings when prefixes are added to it: *epigastric* (above the stomach), *hypogastric* (below the stomach), *endogastric* (within the stomach), and *digastric* (a muscle with two bellies).
- A *suffix* may be added to the end of a word to modify its core meaning. For example, *microscope*, *microscopy*, *microscopic*, and *microscopist* have different meanings because of their suffixes alone. Often two or more suffixes, or a root

¹⁷*epo* = *epi* = upon, based upon; *nym* = name

and suffix, occur together so often that they're treated jointly as a *compound suffix*; for example, *log* (study) + *y* (process) form the compound suffix *-logy* (the study of). Prefixes and suffixes are collectively called *affixes*.

To summarize these basic principles, consider the word *gastroenterology*, a branch of medicine dealing with the stomach and small intestine. It breaks down into *gastro/entero/logy*:

- gastro* = a combining form meaning “stomach”
- entero* = a combining form meaning “small intestine”
- logy* = a compound suffix meaning “the study of”

“Dissecting” words in this way and paying attention to the word-origin footnotes throughout this book will help you become more comfortable with the language of anatomy. Knowing how a word breaks down and knowing the meaning of its elements make it far easier to pronounce a word, spell it, and remember its definition.

There are a few unfortunate exceptions, however. The path from original meaning to current usage has often become obscured by history (see Deeper Insight 1.4). The foregoing approach also is no help with eponyms or **acronyms**¹⁸—words composed of the first letter, or first few letters, of a series of words. For example, a common medical imaging method is the PET scan, an acronym for *positron emission tomography*. Note that PET is a pronounceable word, hence a true acronym. Acronyms are not to be confused with simple abbreviations or *initialisms* such as DNA and MRI, in which each letter must be pronounced separately.

1.7c Plural, Adjective, and Possessive Forms

A point of confusion for many beginning students is how to recognize the plural forms of medical terms. Few people would fail to recognize that *ovaries* is the plural of *ovary*, but the connection is harder to make in other cases: For example, the plural of *cortex* is *cortices* (COR-ti-sees), the plural of *corpus* is *corpora*, and the plural of *ganglion* is *ganglia*. **Table 1.1** will help you make the connection between common singular and plural noun terminals.

In some cases, what appears to the beginner to be two completely different words may be only the noun and adjective forms of the same word. For example, *brachium* denotes the arm, and *brachii* (as in the muscle name *biceps brachii*) means “of the arm.” *Carpus* denotes the wrist, and *carpi*, a word used in several muscle names, means “of the wrist.” Adjectives can also take different forms for the singular and plural and for different degrees of comparison. The *digits* are the fingers and toes. The word *digiti* in a muscle name means “of a single finger (or toe),” whereas *digitorum* is the plural, meaning “of multiple fingers (or toes).” Thus, the *extensor digiti minimi muscle* extends only the little finger, whereas the *extensor digitorum muscle* extends all fingers except the thumb.

DEEPER INSIGHT 1.4
MEDICAL HISTORY

Obscure Medical Word Origins

The literal translation of a word doesn't always provide great insight into its modern meaning. The history of language is full of twists and turns that are fascinating in their own right and say much about the history of human culture, but they can create confusion for students.

For example, the *amnion* is a transparent sac that forms around the developing fetus. The word is derived from *amnos*, from the Greek for “lamb.” From this origin, *amnos* came to mean a bowl for catching the blood of sacrificial lambs, and from there the word found its way into biomedical usage for the membrane that emerges (quite bloody) as part of the afterbirth. The *acetabulum*, the socket of the hip joint, literally means “vinegar cup.” Apparently the hip socket reminded an anatomist of the little cups used to serve vinegar as a condiment on dining tables in ancient Rome. The word *testicles* can be translated “little pots” or “little witnesses.” The history of medical language has several amusing conjectures as to why this word was chosen to name the male gonads.

TABLE 1.1		Singular and Plural Forms of Some Noun Terminals
Singular Ending	Plural Ending	Examples
-a	-ae	axilla, axillae
-en	-ina	lumen, lumina
-ex	-ices	cortex, cortices
-is	-es	diagnosis, diagnoses
-is	-ides	epididymis, epididymides
-ix	-ices	appendix, appendices
-ma	-mata	carcinoma, carcinomata
-on	-a	ganglion, ganglia
-um	-a	septum, septa
-us	-era	viscus, viscera
-us	-i	villus, villi
-us	-ora	corpus, corpora
-x	-ges	phalanx, phalanges
-y	-ies	ovary, ovaries
-yx	-yces	calyx, calyces

The English words *large*, *larger*, and *largest* are examples of the positive, comparative, and superlative degrees of comparison. In Latin, these are *magnus*, *major* (from *maior*), and *maximus*. We find these in the muscle names *adductor magnus* (a *large* muscle of the thigh), the *pectoralis major* (the *larger* of two pectoral muscles of the chest), and *gluteus maximus* (the *largest* of the three gluteal muscles of the buttock).

Some noun variations indicate the possessive, such as the *rectus abdominis*, a straight (*rectus*) muscle of the abdomen (*abdominis*, “of the abdomen”), and the *erector spinae*, a muscle that straightens (*erector*) the spinal column (*spinae*, “of the spine”).

Anatomical terminology also frequently follows the Greek and Latin practice of placing the adjective after the noun. Thus, we

¹⁸*acro* = beginning; *nym* = name

have such names as the *stratum lucidum* for a clear (*lucidum*) layer (*stratum*) of the epidermis, the *foramen magnum* for a large (*magnum*) hole (*foramen*) in the skull, and the aforementioned *pectoralis major* muscle of the chest.

This is not to say that you must be conversant in Latin or Greek grammar to proceed with your study of anatomy. These few examples, however, may alert you to some patterns to watch for in the terminology you study and, ideally, will make your encounters with anatomical terminology less confusing.

1.7d Pronunciation

Pronunciation is another stumbling block for many beginning anatomy and physiology students. This book gives simple pro-NUN-see-AY-shun guides for many terms when they are first introduced. Read the syllables of these guides phonetically and accent the syllables in capital letters. You can also hear pronunciations of most of the anatomical terms within *Anatomy & Physiology Revealed*®.

1.7e The Importance of Spelling

A final word of advice for your study of anatomy and physiology: Be accurate in your spelling and use of terms. It may seem trivial if you misspell *trapezius* as *trapezium*, but in doing so, you would be changing the name of a back muscle to the name of a wrist bone. Similarly, changing *occipitalis* to *occipital* or *zygomaticus* to *zygomatic* changes other muscle names to bone names. Changing *malleus* to *malleolus* changes the name of a middle-ear bone to the name of a bony protuberance of the ankle. And there is only a one-letter difference between *ileum* (the final portion of the small intestine) and *ilium* (part of the hip bone), and between *gustation* (the sense of taste) and *gestation* (pregnancy).

The health professions demand the utmost attention to detail and accuracy—people’s lives may one day be in your hands. The habit of carefulness must extend to your use of language as well. Many patients have died simply because of tragic written and oral miscommunication in the hospital. Compared to this, it is hardly tragic if your instructor deducts a point or two for an error in spelling. It should be considered a lesson learned about the importance of accuracy.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

21. Explain why modern anatomical terminology is so heavily based on Greek and Latin.
22. Distinguish between an eponym and an acronym, and explain why both of these present difficulties for interpreting anatomical terms.
23. Break each of the following words down into its roots, prefixes, and suffixes, and state their meanings, following the example of *gastroenterology* analyzed earlier: *pericardium*, *appendectomy*, *subcutaneous*, *phonocardiogram*, *otorhinolaryngology*. Consult the list of word elements in appendix E for help.
24. Write the singular form of each of the following words: *pleurae*, *gyri*, *ganglia*, *fissures*. Write the plural form of each of the following: *villus*, *tibia*, *encephalitis*, *cervix*, *stoma*.

1.8 Review of Major Themes

To close this chapter, let’s distill a few major points from it. These themes can provide you with a sense of perspective that will make the rest of the book more meaningful and not just a collection of disconnected facts. These are some key unifying principles behind all study of human anatomy and physiology:

- **Unity of form and function.** *Form and function complement each other; physiology cannot be divorced from anatomy.* This unity holds true even down to the molecular level. Our very molecules, such as DNA and proteins, are structured in ways that enable them to carry out their functions. Slight changes in molecular structure can destroy their activity and threaten life.
- **Cell theory.** *All structure and function result from the activity of cells.* Every physiological concept in this book ultimately must be understood from the standpoint of how cells function. Even anatomy is a result of cellular function. If cells are damaged or destroyed, we see the results in disease symptoms of the whole person.
- **Evolution.** *The human body is a product of evolution.* Like every other living species, we have been molded by millions of years of natural selection to function in a changing environment. Many aspects of human anatomy and physiology reflect our ancestors’ adaptations to their environment. Human form and function cannot be fully understood except in light of our evolutionary history.
- **Hierarchy of complexity.** *Human structure can be viewed as a series of levels of complexity.* Each level is composed of a smaller number of simpler subunits than the level above it. These subunits are arranged in different ways to form diverse structures of higher complexity. Understanding the simpler components is the key to understanding higher levels of structure.
- **Homeostasis.** *The purpose of most normal physiology is to maintain stable conditions within the body.* Human physiology is essentially a group of homeostatic mechanisms that produce stable internal conditions favorable to cellular function. Any serious departure from these conditions can be harmful or fatal to cells and thus to the whole body.
- **Gradients and flow.** *Matter and energy tend to flow down gradients* such as differences in chemical concentration, pressure, temperature, and electrical charge. This accounts for much of their movement in human physiology.

▶▶▶ APPLY WHAT YOU KNOW

Architect Louis Henri Sullivan coined the phrase, “Form ever follows function.” What do you think he meant by this? Discuss how this idea could be applied to the human body and cite a specific example of human anatomy to support it.

DEEPER INSIGHT 1.5

CLINICAL APPLICATION

Medical Imaging

The development of techniques for looking into the body without exploratory surgery has greatly accelerated progress in medicine. A few of these techniques are described here.

Radiography

Radiography, first performed in 1895, is the process of photographing internal structures with X-rays (**fig. 1.11a**). Until the 1960s, this was the only widely available imaging method; even today, it accounts for more than 50% of all clinical imaging. X-rays pass through the soft tissues of the body to a photographic film or detector on the other side, where they produce relatively dark images. They are absorbed, however, by dense matter such as bones, teeth, tumors, and tuberculosis nodules, which leave the image lighter in these areas. The term *X-ray* also applies to

an image (*radiograph*) made by this method. Radiography is commonly used in dentistry, mammography, diagnosis of fractures, and examination of the chest. Hollow organs can be visualized by filling them with a contrast medium that absorbs X-rays. Barium sulfate, for example, is given orally for examination of the esophagus, stomach, and small intestine or by enema for examination of the large intestine. Some disadvantages of radiography are that images of overlapping organs can be confusing and slight differences in tissue density are not easily detected. In addition, X-rays can cause mutations leading to cancer and birth defects. Radiography therefore cannot be used indiscriminately.

Blood vessels can be seen especially clearly with a radiographic method called *digital subtraction angiography (DSA)* (**fig. 1.11b**). This entails taking X-rays before and after injecting a contrast medium into a vessel. A

(a) X-ray (radiograph)

(b) Digital subtraction angiogram (DSA)

(c) Computed tomographic (CT) scan

(d) Magnetic resonance image (MRI)

(e) Positron emission tomographic (PET) scan

FIGURE 1.11 Radiologic Images of the Head. (a) X-ray (radiograph) of the skull. (b) Digital subtraction angiogram (DSA) of the cerebral blood vessels. (c) CT scan at the level of the eyes. (d) MRI scan at the level of the eyes. The optic nerves appear in red and the muscles that move the eyes appear in green. (e) A PET scan of the brain of an unmedicated schizophrenic patient. Red areas indicate regions of high metabolic rate. In this patient, the visual center of the brain at the rear of the head (bottom of photo) was especially active during the scan.

? What structures are seen better by MRI than by X-ray? What structures are seen better by X-ray than by PET?

a: U.H.B. Trust/Tony Stone Images/Getty Images;
b: pang_oasis/Shutterstock; c: Miriam Maslo/Science Source; d: UHB Trust/Getty Images; e: ISM/Sovereign Medical Images/DIOMEDIA

computer then “erases” the first image from the second, leaving a clear, dark image of just the injected vessels without the overlying and surrounding tissues. This is useful for showing vascular blockages and anatomical malformations, abnormalities of cerebral blood flow, and narrowing (stenosis) of renal arteries, and as an aid in threading catheters into blood vessels. DSA is already being replaced in many clinics, however, by yet newer methods that are less invasive and avoid contrast medium and radiation exposure.

Computed Tomography

*Computed tomography*¹⁹ (a *CT scan*) (**fig. 1.11c**) is a more sophisticated application of X-rays. The patient is moved through a ring-shaped machine that emits low-intensity X-rays on one side and receives them with a detector on the opposite side. A computer analyzes signals from the detector and produces an image of a “slice” of the body about as thin as a coin. The advantage of such thin planes of view is that there is little overlap of organs, so the image is much sharper than a conventional X-ray. It requires extensive knowledge of cross-sectional anatomy to interpret the images. CT scanning is useful for identifying tumors, aneurysms, cerebral hemorrhages, kidney stones, and other abnormalities.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) (**fig. 1.11d**) is better than CT for visualizing some soft tissues. The patient lies in either a tube or an open-sided scanner surrounded by a powerful electromagnet. Hydrogen atoms in the patient’s tissues alternately align themselves with this magnetic field and with a radio-frequency field turned on and off by the technologist. These changes in hydrogen alignment generate signals that are analyzed by computer to produce an anatomical image. MRI can “see” clearly through the skull and spine to produce images of the nervous tissue within, and it is better than CT for distinguishing between soft tissues such as the white and gray matter of the brain. MRI also avoids X-ray exposure and its risks.

MRI has disadvantages, however, such as the claustrophobic feeling some patients experience in the scanner, loud noises generated by the machine, and long exposure times that prevent sharp images being made of the constantly moving stomach and intestines. It requires a patient to lie still in the enclosed space for up to 45 minutes to scan one region of the body and may entail 90 minutes to scan multiple regions such as the abdominal and pelvic cavities. Some patients find they cannot tolerate this. Open-sided MRI machines are favored by some claustrophobic or obese patients, but have weaker magnetic fields, produce poorer images, and may miss important tissue abnormalities.

Functional MRI (fMRI) is a variation that visualizes moment-to-moment changes in tissue function. fMRI scans of the brain, for example, show shifting patterns of activity as the brain applies itself to a specific sensory, mental, or motor task. fMRI has lately replaced the PET scan as the most important method for visualizing brain function. The use of fMRI in brain imaging is further discussed in Deeper Insight 14.5.

Positron Emission Tomography

Positron emission tomography (the *PET scan*) (**fig. 1.11e**) is used to assess the metabolic state of a tissue and distinguish which tissues are most active at a given moment. The procedure begins with an injection of radioactively labeled glucose, which emits positrons (electron-like particles with a positive charge). When a positron and electron meet, they annihilate each other and give off a pair of gamma rays that can be detected by sensors and analyzed by computer. The computer displays a color image that shows which tissues were using the most glucose at the moment. This is an example of *nuclear*

medicine—the use of radioactive isotopes to treat disease or to form diagnostic images of the body.

PET scans are generally low-resolution, as in this photo, but nevertheless provide valuable diagnostic information. In cardiology, PET scans can show the extent of tissue death from a heart attack. Since it consumes little or no glucose, the damaged tissue appears dark. PET scans are also widely used to diagnose cancer and evaluate tumor status. It is now possible to diagnose Alzheimer disease (AD) with PET scans. Until recently, a definitive diagnosis required analysis of brain tissue after death. Examining living AD patients with PET scans makes earlier diagnosis possible, potentially enabling more effective management of the disease. Conventional PET scans take about 20 minutes, but new technology has enabled three-dimensional, whole-body scans to be made in as little as 20 seconds, with lower radiation exposure. This is helpful in scanning children, who may have difficulty lying still for 20 minutes.

Sonography

*Sonography*²⁰ (**fig. 1.12**) is the second oldest and second most widely used method of imaging. A handheld device pressed against the skin produces high-frequency ultrasound waves and receives the signals that echo back from internal organs. Sonography isn’t very useful for examining bones or lungs, but it is the method of choice in obstetrics, where the image (*sonogram*) can be used to locate the placenta and evaluate fetal age, position, and development. Sonography is also used to view tissues in motion, such as fetal movements, actions of the heart wall and valves, and blood ejection from the heart and flow through arteries and veins. Sonographic imaging of the beating heart is called *echocardiography*. Sonography avoids the harmful effects of X-rays, and the equipment is inexpensive and portable. Some disadvantages are that sonography can’t penetrate bone and it usually doesn’t produce a very sharp image.

FIGURE 1.12 Fetal Sonography. (a) Producing a sonogram. (b) Three-dimensional fetal sonogram at 30 weeks of gestation.

¹⁹tomo = section, cut, slice; *graphy* = recording process

²⁰sono = sound; *graphy* = recording process

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

1.1 The Scope of Anatomy and Physiology

1. The meanings of *anatomy* and *physiology* and what it means to say these two sciences are complementary and inseparable
2. Methods of study in anatomy and clinical examination
3. Branches of anatomy that study the body at different levels of detail
4. How comparative physiology advances the understanding of human function

1.2 The Origins of Biomedical Science

1. Greek and Roman scholars who first gave medicine a scientific basis
2. Ways in which the work of Maimonides, Avicenna, Vesalius, and Harvey were groundbreaking in the context of their time and culture
3. Why medical science today owes such a great debt to Hooke, Leeuwenhoek, and other inventors
4. How Schleiden and Schwann revolutionized and unified the understanding of biological structure, ultimately including human anatomy and physiology

1.3 Scientific Method

1. The essential qualities of the scientific method
2. The nature of the inductive and hypothetico-deductive methods, how they differ, and which areas of biomedical science most heavily employ each method
3. The qualities of a valid scientific hypothesis, the function of a hypothesis, and what is meant by *falsifiability* in science
4. How each of the following contributes to the reliability of a researcher's scientific conclusions and the trust that the public may place in science: sample size, control groups, the double-blind method, statistical testing, and peer review

5. The distinctions between scientific facts, laws, and theories; the purpose of a theory; and how the scientific meanings of *law* and *theory* differ from the common lay meanings

1.4 Human Origins and Adaptations

1. The meanings of *evolution*, *natural selection*, *selection pressure*, and *adaptation*, with examples of each
2. The historical origin of the theory of natural selection and how this theory is relevant to a complete understanding of human anatomy and physiology
3. How the kinship among all species is relevant to the choice of model animals for biomedical research
4. Ecological conditions thought to have selected for such key characteristics of *Homo sapiens* as opposable thumbs, shoulder mobility, prehensile hands, stereoscopic vision, color vision, and bipedal locomotion
5. The meaning of *evolutionary medicine*

1.5 Human Structure

1. Levels of human structural complexity from organism to atom
2. Reductionism and holism; how they differ and why both ideas are relevant to the study of human anatomy and physiology and to the clinical care of patients
3. Examples of why the anatomy presented in textbooks is not necessarily true of every individual

1.6 Human Function

1. Eight essential qualities that distinguish living organisms from nonliving things
2. The meaning of *metabolism*
3. Clinical criteria for life and death, and why clinical and biological death are not exactly equivalent
4. The clinical importance of physiological variation between people, and the

assumptions that underlie typical values given in textbooks

5. The meaning of *homeostasis*; its importance for survival; and the historical origin of this concept
6. How negative feedback contributes to homeostasis; the meaning of *negative feedback loop*; how a receptor, integrating center, and effector are involved in many negative feedback loops; and at least one example of such a loop
7. How positive feedback differs from negative feedback; examples of beneficial and harmful cases of positive feedback
8. The concept of matter and energy flowing down gradients and how this applies to various areas of human physiology

1.7 The Language of Medicine

1. The origin and purpose of the *Terminologia Anatomica (TA)* and its relevance for anatomy students
2. How to break biomedical terms into familiar roots, prefixes, and suffixes, and why the habit of doing so aids in learning
3. Acronyms and eponyms, and why they cannot be understood by trying to analyze their roots
4. How to recognize when two or more words are singular and plural versions of one another; when one word is the possessive form of another; and when medical terms built on the same root represent different degrees of comparison (such as terms denoting *large*, *larger*, and *largest*)
5. Why accuracy in spelling and usage of medical terms can be a matter of life or death in a hospital or clinic, and how seemingly trivial spelling errors can radically alter meaning

1.8 Review of Major Themes

1. A description of six core themes of this book: unity of form and function, cell theory, evolution, hierarchy of complexity, homeostasis, and gradients and flow

STUDY GUIDE

▶ Testing Your Recall

Answers in Appendix A

- Structure that can be observed with the naked eye is called
 - gross anatomy.
 - ultrastructure.
 - microscopic anatomy.
 - histology.
 - cytology.
- The word prefix *homeo-* means
 - tissue.
 - metabolism.
 - change.
 - human.
 - same.
- The simplest structures considered to be alive are
 - organisms.
 - organs.
 - tissues.
 - cells.
 - organelles.
- Which of the following people revolutionized the teaching of gross anatomy?
 - Vesalius
 - Aristotle
 - Hippocrates
 - Leeuwenhoek
 - Cannon
- Which of the following embodies the greatest amount of scientific information?
 - a fact
 - a law of nature
 - a theory
 - a deduction
 - a hypothesis
- An informed, uncertain, but testable conjecture is
 - a natural law.
 - a scientific theory.
 - a hypothesis.
 - a deduction.
 - a scientific fact.
- A self-amplifying chain of physiological events is called
 - positive feedback.
 - negative feedback.
 - dynamic constancy.
 - homeostasis.
 - metabolism.
- Which of the following is *not* a human organ system?
 - integumentary
 - muscular
 - epithelial
 - nervous
 - endocrine
- _____ means studying anatomy by touch.
 - Gross anatomy
 - Auscultation
 - Osculation
 - Palpation
 - Percussion
- The prefix *hetero-* means
 - same.
 - different.
 - both.
 - solid.
 - below.
- Cutting and separating tissues to reveal structural relationships is called _____.
 - A difference in chemical concentration between one point and another is called a concentration _____.
 - By the process of _____, a medical researcher predicts what the result of a certain experiment will be if his or her hypothesis is correct.
 - Physiological effects of a person's mental state are called _____ effects.
 - The tendency of the body to maintain stable internal conditions is called _____.
 - Blood pH averages 7.4 but fluctuates from 7.35 to 7.45. A pH of 7.4 can therefore be considered the _____ for this variable.
 - Self-corrective mechanisms in physiology are called _____ loops.
 - A/an _____ is the simplest body structure to be composed of two or more types of tissue.
 - Depth perception, or the ability to form three-dimensional images, is also called _____ vision.
 - Our hands are said to be _____ because they can encircle an object such as a branch or tool. The presence of an _____ thumb is important to this ability.

▶ Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

STUDY GUIDE

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. The technique for taking a patient's pulse at the wrist is auscultation.
2. For a pregnant woman to have an MRI scan would expose her fetus to radiation that can potentially cause mutation and birth defects.
3. We usually depend on positive feedback to restore homeostatic balance and have a beneficial effect on the body.
4. There are far more cells than organelles in the body.
5. Matter doesn't generally move down a gradient in the body unless the body expends metabolic energy to move it.
6. Leeuwenhoek was a biologist who invented the simple microscope in order to examine organisms in lake water.
7. A scientific theory is just a speculation until someone finds the evidence to prove it.
8. In a typical clinical research study, volunteer patients are in the treatment group and the physicians and scientists who run the study constitute the control group.
9. Human evolution is basically a theory that humans came from monkeys.
10. Negative feedback usually has a negative (harmful) effect on the body.

► Testing Your Comprehension

1. Ellen is pregnant and tells Janet, one of her coworkers, that she is scheduled to get a fetal sonogram. Janet expresses alarm and warns Ellen about the danger of exposing a fetus to X-rays. Discuss why you think Janet's concern is warranted or unwarranted.
2. Which of the characteristics of living things are possessed by an automobile? What bearing does this have on our definition of life?
3. About 1 out of every 120 live-born infants has a structural defect in the heart such as a hole between two heart chambers. Such infants often suffer pulmonary congestion and heart failure, and about one-third of them die as a result. Which of the major themes in this chapter does this illustrate? Explain your answer.
4. How might human anatomy be different today if the forerunners of humans had never inhabited the forest canopy?
5. Suppose you have been doing heavy yard work on a hot day and sweating profusely. You become very thirsty, so you drink a tall glass of lemonade. Explain how your thirst relates to the concept of homeostasis. Which type of feedback—positive or negative—does this illustrate?

DEEPER INSIGHTS

A.1 Clinical Application: Cardiac Tamponade

A.2 Clinical Application: Peritonitis

Module 1: Body Orientation

A.1 General Anatomical Terminology

A.1a Anatomical Position

In describing the human body, anatomists assume that it is in **anatomical position** (fig. A.1)—that is, standing upright with the feet flat on the floor, arms at the sides, and the palms and face directed forward. Without such a frame of reference, to say that a structure such as the sternum, thyroid gland, or aorta is “above the heart” would be vague, since it would depend on whether the subject was standing, lying face down (*prone*), or lying face up (*supine*). From the perspective of anatomical position, however, we can describe the thyroid as *superior* to the heart, the sternum as *anterior* to it, and the aorta as *posterior* to it. These descriptions remain valid regardless of the subject’s position. Even if the body is lying down, such as a cadaver on a dissection table, to say the sternum is anterior to the heart invites the viewer to imagine the body is standing in anatomical position and not to call it “above the heart” simply because that is the way the body happens to be lying.

Unless stated otherwise, assume that all anatomical descriptions refer to anatomical position. Bear in mind that if a subject is facing you, the subject’s left is on your right and vice versa. In most anatomical illustrations, for example, the left atrium of the

heart appears toward the right side of the page, and although the appendix is located in the right lower quadrant of the abdomen, it appears on the left side of most illustrations.

A.1b Anatomical Planes

Many views of the body are based on real or imaginary “slices” called sections or planes. *Section* implies an actual cut or slice to reveal internal anatomy, whereas *plane* implies an imaginary flat surface passing through the body. The three primary anatomical planes are *sagittal*, *frontal*, and *transverse* (fig. A.1).

A **sagittal**¹ plane (SADJ-ih-tul) passes vertically through the body or an organ and divides it into right and left portions (fig. A.2a). The sagittal plane that divides the body or organ into equal halves is also called the **median (midsagittal) plane**. The head and pelvic organs are commonly illustrated on the median plane. Other sagittal planes parallel to this (off center) divide the body into unequal portions. Such planes are sometimes called *parasagittal*² planes.

A **frontal (coronal) plane** also extends vertically, but it is perpendicular to the sagittal plane and divides the body into anterior (front) and posterior (back) portions (fig. A.2b). A frontal section

¹sagitta = arrow

FIGURE A.2 Body Sections Cut Along the Three Primary Anatomical Planes. (a) Sagittal section of the pelvic region. (b) Frontal section of the thoracic region. (c) Transverse section of the head at the level of the eyes.

TABLE A.1 Directional Terms in Human Anatomy 		
Term	Meaning	Examples of Usage
Ventral Dorsal	Toward the front* or belly Toward the back or spine	The aorta is ventral to the vertebral column. The vertebral column is dorsal to the aorta.
Anterior Posterior	Toward the ventral side* Toward the dorsal side*	The sternum is anterior to the heart. The esophagus is posterior to the trachea.
Cephalic Rostral Caudal	Toward the head or superior end Toward the forehead or nose Toward the tail or inferior end	The brain develops from the cephalic end of the neural tube. The forebrain is rostral to the brainstem. The spinal cord is caudal to the brain.
Superior Inferior	Above Below	The heart is superior to the diaphragm. The liver is inferior to the diaphragm.
Medial Lateral	Toward the median plane Away from the median plane	The heart is medial to the lungs. The eyes are lateral to the nose.
Proximal Distal	Closer to the point of attachment or origin Farther from the point of attachment or origin	The elbow is proximal to the wrist. The fingernails are at the distal ends of the fingers.
Ipsilateral Contralateral	On the same side of the body (right or left) On opposite sides of the body (right and left)	The liver is ipsilateral to the appendix. The spleen is contralateral to the liver.
Superficial Deep	Closer to the body surface Farther from the body surface	The skin is superficial to the muscles. The bones are deep to the muscles.

*In humans only; definition differs for other animals.

of the head, for example, divides it into one portion bearing the face and another bearing the back of the head. Contents of the thoracic and abdominal cavities are usually shown as frontal sections.

A **transverse (horizontal) plane** passes across the body or an organ perpendicular to its long axis; it divides the body or organ into superior (upper) and inferior (lower) portions (**fig. A.2c**). CT scans are typically transverse sections (see **fig. 1.11c**).

A.1c Directional Terms

Words that describe the location of one structure relative to another are called the **directional terms** of anatomy. **Table A.1** summarizes those most frequently used. Most of these terms exist in pairs with opposite meanings: *anterior* versus *posterior*, *rostral* versus *caudal*, *superior* versus *inferior*, *medial* versus *lateral*, *proximal* versus *distal*, *ipsilateral* versus *contralateral*, and *superficial* versus *deep*. Intermediate directions are often indicated by combinations of these terms. For example, one’s cheeks may be described as *inferolateral* to the eyes (below and to the side).

The terms *proximal* and *distal* are used especially in the anatomy of the limbs, with ***proximal*** used to denote something relatively close to the limb’s point of attachment (the shoulder or hip) and ***distal*** to denote something farther away. These terms do have some applications to anatomy of the trunk, however—for example, in referring to certain aspects of the intestines and microscopic anatomy of the kidneys. But when describing the trunk and referring to a structure that lies above or below another, ***superior*** and ***inferior*** are the preferred terms. These terms aren’t usually used for the limbs. Although it may be technically correct, one wouldn’t generally say the elbow is superior to the wrist, but proximal to it.

Because of the bipedal, upright stance of humans, some directional terms have different meanings for humans than they do for other animals. ***Anterior***, for example, denotes the region of the body that leads the way in normal locomotion. For a four-legged animal such as a cat, this is the head end of the body; for a human, however, it is the front of the chest and abdomen. Thus, *anterior* has the same meaning as *ventral* for a human but not for a cat. ***Posterior*** denotes the region of the body that comes last in normal locomotion—the tail end of a cat but the dorsal side (back) of a human. In the anatomy of most other animals, *ventral* denotes the surface of the body closest to the ground and *dorsal* denotes the surface farthest away from the ground. These two words are too entrenched in human anatomy to completely ignore them, but we will minimize their use in this book to avoid confusion. You must keep such differences in mind, however, when dissecting other animals for comparison to human anatomy.

A derivative of the term *dorsal* is ***dorsum***, used to denote the upper surface of the foot and the back of the hand. If you consider how a cat stands, the corresponding surfaces of its paws are uppermost, facing the same direction as the dorsal side of its trunk. Although these surfaces of the human hand and foot face entirely different directions in anatomical position, the term *dorsum* is still used.

A.2 Major Body Regions

Knowledge of the external anatomy and landmarks of the body is important in performing a physical examination and many other clinical procedures. For purposes of study, the body is divided into two major regions called the *axial* and *appendicular* regions. Smaller areas within the major regions are described in the following paragraphs and illustrated in **figure A.3**.

FIGURE A.3 The Adult Female and Male Body Regions. (a) Female, anterior. (b) Male, anterior. (c) Female, posterior. (d) Male, posterior.

FIGURE A.4 The Four Quadrants and Nine Regions of the Abdomen.

(a) External division into four quadrants.
(b) External division into nine regions.

APR

? In what quadrant would the pain of appendicitis usually be felt?

A.2a Axial Region

The **axial region** consists of the **head**, **neck** (**cervical**³ **region**), and **trunk**. The trunk is further divided into the **thoracic region** above the diaphragm and the **abdominal region** below it.

One way of referring to the locations of abdominal structures is to divide the region into quadrants. Two perpendicular lines intersecting at the umbilicus (navel) divide the abdomen into a **right upper quadrant (RUQ)**, **right lower quadrant (RLQ)**, **left upper quadrant (LUQ)**, and **left lower quadrant (LLQ)** (**fig. A.4a**). The quadrant scheme is often used to describe the site of an abdominal pain or abnormality.

The abdomen also can be divided into nine regions defined by four lines that intersect like a tic-tac-toe grid (**fig. A.4b**). Each vertical line is called a **midclavicular line** because it passes through the midpoint of the clavicle (collarbone). The superior horizontal line is called the **subcostal**⁴ **line** because it connects the inferior borders of the lowest costal cartilages (cartilage connecting the tenth rib on each side to the inferior end of the sternum). The inferior horizontal line is called the **intertubercular**⁵ **line** because it passes from left to right between the tubercles (*anterior superior spines*) of the pelvis—two points of bone located about where the front pockets open on most pants. The three lateral regions of this grid, from upper to lower, are the **hypochondriac**,⁶ **lumbar**, and **inguinal**⁷ (**iliac**) **regions**. The three medial regions from upper to lower are the **epigastric**,⁸ **umbilical**, and **hypogastric** (**pubic**) **regions**.

A.2b Appendicular Region

The **appendicular region** (AP-en-DIC-you-lur) of the body consists of the **upper** and **lower limbs** (also called *appendages* or *extremities*). The upper limb includes the **arm** (**brachial region**) (BRAY-kee-ul), **forearm** (**antebrachial**⁹ **region**) (AN-teh-BRAY-kee-ul), **wrist** (**carpal region**), **hand**, and **fingers** (**digits**). The lower limb includes the **thigh** (**femoral region**), **leg** (**crural region**) (CROO-rul), **ankle** (**tarsal region**), **foot**, and **toes** (**digits**). In strict anatomical terms, *arm* refers only to that part of the upper limb between the shoulder and elbow. *Leg* refers only to that part of the lower limb between the knee and ankle.

A **segment** of a limb is a region between one joint and the next. The arm, for example, is the segment between the shoulder and elbow, and the forearm is the segment between the elbow and wrist. Flexing your fingers, you can easily see that your thumb has two segments (proximal and distal), whereas the other four digits have three segments (proximal, middle, and distal). The segment concept is especially useful in describing the locations of bones and muscles and the movements of the joints.

A.3 Body Cavities and Membranes

The body wall encloses multiple **body cavities** (**fig. A.5, table A.2**), each lined with a membrane and containing internal organs called **viscera** (VISS-er-uh) (singular, *viscus*¹⁰). Some of these membranes are two-layered, having one layer against the organ surface (such as the heart or lung) and one layer against a surrounding structure (forming, for example, the inner lining of the rib cage); there

³cervic = neck

⁴sub = below; cost = rib

⁵inter = between; tubercul = little swelling

⁶hypo = below; chondr = cartilage

⁷inguin = groin

⁸epi = above, over; gastr = stomach

⁹ante = fore, before; brachi = arm

¹⁰viscus = body organ

FIGURE A.5 The Major Body Cavities. (a) Left lateral view. (b) Anterior view.

TABLE A.2 Body Cavities and Membranes APR		
Name of Cavity	Associated Viscera	Membranous Lining
Cranial cavity	Brain	Meninges
Vertebral canal	Spinal cord	Meninges
Thoracic cavity		
Pleural cavities (2)	Lungs	Pleurae
Pericardial cavity	Heart	Pericardium
Abdominopelvic cavity		
Abdominal cavity	Digestive organs, spleen, kidneys	Peritoneum
Pelvic cavity	Urinary bladder, rectum, reproductive organs	Peritoneum

is only a thin film of liquid between them. In such cases, the inner layer, against the organ, is called the **visceral layer** (VISS-er-ul) of the membrane, and the more superficial or outer one, the **parietal**¹¹ layer (pa-RY-eh-tul).

A.3a Cranial Cavity and Vertebral Canal

The **cranial cavity** is enclosed by the cranium (braincase) and contains the brain. The **vertebral canal** is enclosed by the vertebral column (spine) and contains the spinal cord. The two are

continuous with each other and are lined by three membrane layers called the **meninges** (meh-NIN-jeez). Among other functions, the meninges protect the delicate nervous tissue from the hard protective bone that encloses it.

A.3b Thoracic Cavity

The trunk of your body contains two major spaces, the thoracic cavity and abdominopelvic cavity, separated by a transverse muscular sheet, the **diaphragm**. Superior to the diaphragm, in your chest, is the **thoracic cavity**, and inferior to it, in your abdomen, is the **abdominopelvic cavity**. Both cavities are lined with thin **serous membranes**, which secrete a lubricating film of moisture similar to blood serum (hence their name).

The thoracic cavity is divided by a thick median wall called the **mediastinum**¹² (ME-dee-ah-STY-num) (**fig. A.5b**). This is the region between the lungs, extending from the base of the neck to the diaphragm. It is occupied by the heart, the major blood vessels connected to it, the esophagus, the trachea and bronchi, and a gland called the thymus.

The heart is enfolded in a two-layered membrane called the **pericardium**.¹³ The inner layer of the pericardium forms the surface of the heart itself and is called the **visceral layer**. The outer layer is called the **parietal layer**. These layers are separated by a space called the **pericardial cavity** (**fig. A.6a**), which is lubricated by **pericardial fluid**. This space allows the heart freedom of movement during its contraction and relaxation, but can pose a life-threatening problem if it fills with serous fluid or blood (see Deeper Insight A.1).

¹¹pariet = wall

¹²mediastinum = in the middle

¹³peri = around; cardi = heart

FIGURE A.6 Parietal and Visceral Layers of Double-Walled Membranes. (a) Relationship of the pericardium to the heart. (b) Relationship of the pleurae to the lungs.

DEEPER INSIGHT A.1

CLINICAL APPLICATION

Cardiac Tamponade

Being confined by the pericardium can cause a problem for the heart under some circumstances. If a heart wall weakened by disease should rupture, or if it suffers a penetrating injury such as a knife or gunshot wound, blood spurts from the heart into the pericardial cavity, filling the cavity more and more with each heartbeat. Diseased hearts also sometimes seep serous fluid into the pericardial sac. Either way, the effect is the same: The pericardial sac has little room to expand, so the accumulating fluid puts pressure on the heart, squeezing it and preventing it from refilling between beats. This condition is called **cardiac tamponade**. If the heart chambers cannot refill, then cardiac output declines and a person may die of catastrophic circulatory failure. A similar situation occurs if serous fluid or air accumulates in the pleural cavity, causing collapse of a lung.

The right and left sides of the thoracic cavity contain the lungs. Each lung is enfolded by a serous membrane called the **pleura**¹⁴ (PLOOR-uh) (**fig. A.6b**). Like the pericardium, the pleura has visceral (inner) and parietal (outer) layers. The **visceral pleura** forms the external surface of the lung, and the **parietal pleura** lines the inside of the rib cage. The narrow space between them is called the **pleural cavity** (see fig. B.11 in atlas B, following chapter 10). It is lubricated by slippery **pleural fluid**.

Note that in both the pericardium and the pleura, the visceral layer of the membrane *covers* an organ surface and the parietal layer *lines* the inside of a body cavity. We will see this pattern elsewhere, including the abdominopelvic cavity.

A.3c Abdominopelvic Cavity

The abdominopelvic cavity consists of the **abdominal cavity** superiorly and the **pelvic cavity** inferiorly. The abdominal cavity contains most of the digestive organs as well as the spleen, kidneys, and ureters. It extends inferiorly to the level of a bony landmark called the *brim* of the pelvis (see figs. B.7 and 8.37b). The pelvic cavity, below the brim, is continuous with the abdominal cavity (no wall separates them), but it is markedly narrower and tilts posteriorly (see fig. A.5a). It contains the rectum, urinary bladder, urethra, and reproductive organs.

The abdominopelvic cavity contains a two-layered serous membrane called the **peritoneum**¹⁵ (PERR-ih-toe-NEE-um). Its outer layer, the **parietal peritoneum**, lines the cavity wall. Along the posterior midline, it turns inward and becomes another layer, the **visceral peritoneum**, suspending certain abdominal viscera from the body wall, covering their outer surfaces, and holding them in place. The **peritoneal cavity** is the space between the parietal and visceral layers. It is lubricated by **peritoneal fluid**.

Some organs of the abdominal cavity lie against the posterior body wall and are covered by peritoneum only on the side facing the peritoneal cavity. They are said to have a **retroperitoneal**¹⁶ position (“behind the peritoneum”) (**fig. A.7**). These include the kidneys, ureters, adrenal glands, most of the pancreas, and abdominal portions of two major blood vessels—the aorta and inferior vena cava (see fig. B.6). Organs that are encircled by peritoneum and connected to the posterior body wall by peritoneal sheets are described as **intraperitoneal**.¹⁷

The visceral peritoneum is also called a **mesentery**¹⁸ (MESS-en-tare-ee) at points where it forms a translucent, membranous

¹⁴pleur = rib, side

¹⁵peri = around; tone = stretched

¹⁶retro = behind

¹⁷intra = within

¹⁸mes = in the middle; enter = intestine

b: MediciImage/Universal Images Group/Getty Images

curtain suspending and anchoring the viscera (**fig. A.8**), and a **serosa** (seer-OH-sa) at points where it enfolds and covers the outer surfaces of organs such as the stomach and small intestine. There is only one mesentery in the abdomen, but it folds in such a complex way around the intestines that it long gave anatomists the impression of several separate mesenteries. We still use more specific names, however, for different regions of the one mesentery. The intestines are suspended from the posterior (dorsal) abdominal wall

by the **posterior mesentery**. The posterior mesentery of the large intestine is called the **mesocolon**. In some places, after wrapping around the intestines or other viscera, the mesentery continues toward the anterior body wall as the **anterior mesentery**. The most significant example of this is a fatty membrane called the **greater omentum**,¹⁹ which hangs like an apron from the inferolateral

¹⁹ *omentum* = covering

DEEPER INSIGHT A.2

CLINICAL APPLICATION

Peritonitis

Peritonitis is inflammation of the peritoneum. It is a critical, life-threatening condition necessitating prompt treatment. The most serious cause of peritonitis is a perforation in the digestive tract, such as a ruptured appendix or a gunshot wound. Digestive juices cause immediate chemical inflammation of the peritoneum, followed by microbial inflammation as intestinal bacteria invade the body cavity. Anything that perforates the abdominal wall can also lead to peritonitis—for example, surgery, gunshot wounds, and stab wounds. So, too, can free blood in the abdominal cavity, as from a ruptured aneurysm (a weak point in a blood vessel) or ectopic pregnancy (implantation of an embryo anywhere other than the uterus); blood itself is a chemical irritant to the peritoneum. Peritonitis tends to shift fluid from the circulation into the abdominal cavity. Death can follow within a few days from severe electrolyte imbalance, respiratory distress, kidney failure, and widespread blood clotting called *disseminated intravascular coagulation*.

margin of the stomach and overlies the intestines (figs. A.8a and B.4). The greater omentum is unattached at its inferior border and can be lifted to reveal the intestines. A smaller **lesser omentum** extends from the superomedial margin of the stomach to the liver.

A.3d Potential Spaces

Some of the spaces between body membranes are considered to be **potential spaces**, so named because under normal conditions, the membranes are pressed firmly together and there is no actual space between them. The membranes aren't physically attached, however, and under unusual conditions, they may separate and create a space filled with fluid or other matter. Thus there is normally no actual space, but only a potential for membranes to separate and create one.

The pleural cavity is one example. Normally the parietal and visceral pleurae are pressed together without a gap between them, but under pathological conditions, air or serous fluid can accumulate between the membranes and open up a space. The internal cavity (**lumen**) of the uterus is another. In a nonpregnant uterus, the mucous membranes of opposite walls are pressed together so there is no open space in the organ. In pregnancy, of course, a growing fetus occupies this space and pushes the mucous membranes apart.

A.4 Organ Systems

The human body has 11 **organ systems** (fig. A.9) and an immune system, which is better described as a population of cells that inhabit multiple organs rather than as an organ system. The organ systems are classified in the following list by their principal functions, but this is an imperfect classification. Some organs belong to two or more systems—for example, the male urethra is part of both the urinary and reproductive systems; the pancreas is part of the endocrine and digestive systems; and the mammary glands can be considered part of the integumentary and female reproductive systems. The organ systems are as follows:

Systems of protection, support, and movement

- Integumentary system
- Skeletal system
- Muscular system

Systems of internal communication and control

- Nervous system
- Endocrine system

Systems of fluid transport

- Circulatory system
- Lymphatic system

Systems of intake and output

- Respiratory system
- Urinary system
- Digestive system

Systems of reproduction

- Male reproductive system
- Female reproductive system

Some medical terms combine the names of two systems—for example, the *musculoskeletal system*, *cardiopulmonary system*, and *urogenital (genitourinary) system*. These terms serve to call attention to the close anatomical or physiological relationships between two systems, but these are not literally individual organ systems.

Principal organs:
Skin, hair, nails,
cutaneous glands

Principal functions:
Protection, water retention,
thermoregulation,
vitamin D synthesis,
cutaneous sensation,
nonverbal communication

Integumentary system

Principal organs:
Bones, cartilages,
ligaments

Principal functions:
Support, movement,
protective enclosure of
viscera, blood formation,
mineral storage,
electrolyte and acid–base
balance

Skeletal system

Principal organs:
Skeletal muscles

Principal functions:
Movement, stability,
communication, control
of body openings, heat
production

Muscular system

Principal organs:
Lymph nodes,
lymphatic vessels,
thymus, spleen, tonsils

Principal functions:
Recovery of excess
tissue fluid, detection of
pathogens, production
of immune cells, defense
against disease

Lymphoid system

Principal organs:
Nose, pharynx, larynx,
trachea, bronchi, lungs

Principal functions:
Absorption of oxygen,
discharge of carbon
dioxide, acid–base
balance, speech

Respiratory system

Principal organs:
Kidneys, ureters, urinary
bladder, urethra

Principal functions:
Elimination of wastes;
regulation of blood
volume and pressure;
stimulation of red blood
cell formation; control
of fluid, electrolyte,
and acid–base balance;
detoxification

Urinary system

FIGURE A.9 The Human Organ Systems.

FIGURE A.9 The Human Organ Systems (continued).

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

A.1 General Anatomical Terminology

1. Anatomical position and why it is important for anatomical description
2. Directions along which the body or an organ is divided by the sagittal, frontal, and transverse planes; how the median plane differs from other sagittal planes
3. Meanings of each of the following pairs or groups of terms, and the ability to describe the relative locations of two body parts using these terms: *ventral* and *dorsal*; *anterior* and *posterior*; *cephalic*, *rostral*, and *caudal*; *superior* and *inferior*; *medial* and *lateral*; *proximal* and *distal*; *superficial* and *deep*
4. Why the terms *ventral* and *dorsal* are ambiguous in human anatomy but less so in most other animals; what terms are used in their place in human anatomy; and reasons why they are occasionally appropriate or unavoidable in human anatomy

A.2 Major Body Regions

1. Distinctions between the axial and appendicular regions of the body
2. Subdivisions of the axial region and landmarks that divide and define them
3. The abdomen's four quadrants and nine regions; their defining landmarks; and why this scheme is clinically useful
4. The segments of the upper and lower limbs; how the anatomical meanings of *arm* and *leg* differ from the colloquial meanings

A.3 Body Cavities and Membranes

1. Locations and contents of the cranial cavity, vertebral canal, thoracic cavity, and abdominopelvic cavity; the membranes that line them; and the main viscera contained in each
2. Contents of the mediastinum and its relationship to the thoracic cavity as a whole
3. The pericardium, its two layers, the space and fluid between the layers, and its function
4. The pleurae, their two layers, the space and fluid between the layers, and their function

5. The two subdivisions of the abdominopelvic cavity and the skeletal landmark that divides them
6. The peritoneum; its functions; its two layers and their relationship to the abdominal viscera; and the peritoneal fluid
7. Mesenteries and serosae
8. Intraperitoneal versus retroperitoneal organs, examples of both, and how one would identify an organ as being intra- or retroperitoneal
9. Names and locations of the posterior and anterior mesenteries
10. The serosa of an abdominopelvic organ and how it relates to the peritoneum
11. Examples of potential spaces and why they are so named

A.4 Organ Systems

1. The 11 organ systems, the functions of each, and the principal organs of each system

► Testing Your Recall

Answers in Appendix A

1. Which of the following is *not* an essential part of anatomical position?
 - a. feet together
 - b. feet flat on the floor
 - c. palms forward
 - d. mouth closed
 - e. arms down to the sides
2. A ring-shaped section of the small intestine would be a _____ section.
 - a. sagittal
 - b. coronal
 - c. transverse
 - d. frontal
 - e. median
3. The tarsal region is _____ to the popliteal region.
 - a. medial
 - b. superficial
 - c. superior
 - d. dorsal
 - e. distal
4. The greater omentum is _____ to the small intestine.
 - a. posterior
 - b. parietal
 - c. deep
 - d. superficial
 - e. proximal
5. A _____ plane passes through the sternum, umbilicus, and mons pubis.
 - a. central
 - b. proximal
 - c. midclavicular
 - d. midsagittal
 - e. intertubercular
6. The _____ region is immediately medial to the coxal region.
 - a. inguinal
 - b. hypochondriac
 - c. umbilical
 - d. popliteal
 - e. cubital
7. Which of the following regions is not part of the upper limb?
 - a. plantar
 - b. carpal
 - c. cubital
 - d. brachial
 - e. palmar
8. Which of these organs is within the peritoneal cavity?
 - a. urinary bladder
 - b. kidneys
 - c. heart
 - d. liver
 - e. brain
9. In which area do you think pain from the gallbladder would be felt?
 - a. umbilical region
 - b. right upper quadrant
 - c. hypogastric region
 - d. left hypochondriac region
 - e. left lower quadrant

STUDY GUIDE

10. Which organ system regulates blood volume, controls acid–base balance, and stimulates red blood cell production?
 - a. digestive system
 - b. lymphatic system
 - c. nervous system
 - d. urinary system
 - e. circulatory system
11. The translucent membrane that suspends the intestines and holds them in place is called the _____.
12. The superficial layer of the pleura is called the _____ pleura.
13. The right and left pleural cavities are separated by a thick wall called the _____.
14. The back of the neck is the _____ region.
15. If two organs are on opposite sides of the body (right and left), we say they are _____ to each other.
16. The cranial cavity is lined by membranes called the _____.
17. Organs that lie within the abdominal cavity but not within the peritoneal cavity are said to have a _____ position.
18. The sternal region is _____ to the pectoral region.
19. The pelvic cavity can be described as _____ to the abdominal cavity in position.
20. The anterior pit of the elbow is the _____ region, and the corresponding (but posterior) pit of the knee is the _____ region.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this atlas that uses it or a slight variation of it.

- | | | |
|-------------|-------------|--------------|
| 1. ante- | 3. epi- | 7. parieto- |
| 2. cervico- | 4. hypo- | 8. peri- |
| | 5. inguino- | 9. retro- |
| | 6. intra- | 10. sagitto- |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|---|--|--|
| 1. Both lungs could be shown in one sagittal section of the body. | 4. The diaphragm is posterior to the lungs. | 8. The kidneys are in the peritoneal cavity of the abdomen. |
| 2. A single frontal section of the head cannot include both eyes. | 5. The esophagus is inferior to the stomach. | 9. The peritoneum lines the inside of the stomach and intestines. |
| 3. The knee is distal to the tarsal region. | 6. The liver is in the lumbar region. | 10. The sigmoid colon is in the lower right quadrant of the abdomen. |
| | 7. The heart is in the space between the parietal and visceral pericardium, called the pericardial cavity. | |

► Testing Your Comprehension

- | | | |
|--|--|---|
| 1. Identify which anatomical plane—sagittal, frontal, or transverse—is the only one that could <i>not</i> show (a) both the brain and tongue, (b) both eyes, (c) both the hypogastric and gluteal regions, (d) both kidneys, (e) both the sternum and vertebral column, and (f) both the heart and uterus. | really mean when they say they have “planter’s warts”? | 4. Based on the illustrations in this atlas, identify an internal organ that is (a) in the upper left quadrant and retroperitoneal, (b) in the lower right quadrant of the peritoneal cavity, (c) in the hypogastric region, (d) in the right hypochondriac region, and (e) in the pectoral region. |
| 2. Laypeople often misunderstand anatomical terminology. What do you think people | 3. Name one structure or anatomical feature that could be found in each of the following locations relative to the ribs: medial, lateral, superior, inferior, deep, superficial, posterior, and anterior. Try not to use the same example twice. | 5. Why do you think people with imaginary illnesses came to be called hypochondriacs? |

THE CHEMISTRY OF LIFE

Cell-membrane proteins governing interaction between an immune cell (T lymphocyte) at bottom and an antigen-presenting cell (APC) at the top. This image was generated by pairing a supercomputer with a cryo-electron microscope (cryo-EM) to view molecules at the atomic level.

CHAPTER OUTLINE

2.1 Atoms, Ions, and Molecules

- 2.1a The Chemical Elements
- 2.1b Atomic Structure
- 2.1c Isotopes and Radioactivity
- 2.1d Ions, Electrolytes, and Free Radicals
- 2.1e Molecules and Chemical Bonds

2.2 Water and Mixtures

- 2.2a Water
- 2.2b Solutions, Colloids, and Suspensions
- 2.2c Acids, Bases, and pH
- 2.2d Other Measures of Concentration

2.3 Energy and Chemical Reactions

- 2.3a Energy and Work
- 2.3b Classes of Chemical Reactions
- 2.3c Reaction Rates
- 2.3d Metabolism, Oxidation, and Reduction

2.4 Organic Compounds

- 2.4a Carbon Compounds and Functional Groups
- 2.4b Monomers and Polymers
- 2.4c Carbohydrates
- 2.4d Lipids
- 2.4e Proteins
- 2.4f Enzymes and Metabolism
- 2.4g ATP, Other Nucleotides, and Nucleic Acids

Study Guide

DEEPER INSIGHTS

2.1 Medical History: Radiation and Madame Curie

2.2 Clinical Application: pH and Drug Action

2.3 Clinical Application: *Trans* Fats and Cardiovascular Health

2.4 Clinical Application: “Good” and “Bad” Cholesterol

2.5 Clinical Application: Enzymes as Disease Markers

2.6 Clinical Application: Steroid Abuse

Module 2: Cells and Chemistry

BRUSHING UP

Beginning here, each chapter builds on information presented in earlier ones. If you don't clearly remember these concepts, you may find that brushing up on them before you proceed will enable you to get more out of each new chapter.

- “Characteristics of Life” in section 1.6a introduces metabolism as one of the most fundamental human functions. Here we will delve more deeply into metabolism and its two subdivisions, anabolism and catabolism.

Why is too much sodium or cholesterol harmful? Why does an iron deficiency cause anemia and an iodine deficiency cause a goiter? Why does a pH imbalance make some drugs less effective? Why do some pregnant women suffer convulsions after several days of vomiting? How can radiation cause cancer as well as cure it?

None of these questions can be answered, nor would the rest of this book be intelligible, without understanding the chemistry of life. A little knowledge of chemistry can help you choose a healthy diet, use medications more wisely, avoid worthless health fads and frauds, and explain treatments and procedures to your patients or clients. Thus, we begin our study of the human body with basic chemistry, the simplest level of the body's structural organization.

We will progress from general chemistry to **biochemistry**, study of the molecules that compose living organisms—especially molecules unique to living things, such as carbohydrates, fats, proteins, and nucleic acids. Most people have at least heard of these; it's common knowledge that we need proteins, fats, carbohydrates, vitamins, and minerals in our diet, and that we should avoid consuming too much saturated fat and cholesterol. But most people have only a vague concept of what these molecules are, much less how they function in the body. Such knowledge is very helpful in matters of personal fitness and patient education and is essential to the comprehension of the rest of this book.

2.1 Atoms, Ions, and Molecules

Expected Learning Outcomes

When you have completed this section, you should be able to

- identify the elements of the body from their symbols;
- distinguish between elements and compounds;
- state the functions of minerals in the body;
- explain the basis for radioactivity and the types and hazards of ionizing radiation;
- distinguish between ions, electrolytes, and free radicals; and
- define the types of chemical bonds.

2.1a The Chemical Elements

A chemical **element** is the simplest form of matter to have unique chemical properties. Water, for example, is not an element; it has unique properties, but it can be broken down into two elements, hydrogen and oxygen, that have unique chemical properties of their own. If we carry this process any further, however, we find that hydrogen and oxygen are made of protons, neutrons, and electrons—and none of these are unique. A proton of gold is identical to a proton of oxygen. Hydrogen and oxygen are the simplest chemically unique components of water and are thus elements.

Each element is identified by an *atomic number*, the number of protons in its nucleus. The atomic number of carbon is 6 and that of oxygen is 8, for example. The periodic table of the elements (see appendix C) arranges the elements in order by their atomic numbers. Elements are represented by one- or two-letter symbols, usually suggesting their English names: C for carbon, Mg for magnesium, Cl for chlorine, and so forth. A few symbols represent their original Latin names, such as K for potassium (*kalium*), Na for sodium (*natrium*), and Fe for iron (*ferrum*).

There are 91 naturally occurring elements on earth, 24 of which play normal physiological roles in humans. **Table 2.1** groups these 24 according to their abundance in the body. Six of them account for 98.5% of the body's weight: oxygen, carbon, hydrogen, nitrogen, calcium, and phosphorus. The next 0.8% consists of another 6 elements: sulfur, potassium, sodium, chlorine, magnesium, and iron. The remaining 12 elements total only 0.7% of body weight; thus, they are known as **trace elements**. Despite their minute quantities, trace

TABLE 2.1

Elements of the Human Body

Name and Symbol	Percentage of Body Weight	Name and Symbol	Percentage of Body Weight
Major Elements (Total 98.5%)			
Oxygen (O)	65.0	Nitrogen (N)	3.0
Carbon (C)	18.0	Calcium (Ca)	1.5
Hydrogen (H)	10.0	Phosphorus (P)	1.0
Lesser Elements (Total 0.8%)			
Sulfur (S)	0.25	Chlorine (Cl)	0.15
Potassium (K)	0.20	Magnesium (Mg)	0.05
Sodium (Na)	0.15	Iron (Fe)	0.006
Trace Elements (Total 0.7%) (Names and symbols only)			
Chromium (Cr)	Fluorine (F)	Molybdenum (Mo)	Tin (Sn)
Cobalt (Co)	Iodine (I)	Selenium (Se)	Vanadium (V)
Copper (Cu)	Manganese (Mn)	Silicon (Si)	Zinc (Zn)

elements play vital roles in physiology. Other elements without natural physiological roles can contaminate the body and severely disrupt its functions, as in heavy-metal poisoning with lead or mercury.

Several of these elements are classified as **minerals**—inorganic elements extracted from the soil by plants and passed up the food chain to humans and other organisms. Minerals constitute about 4% of the human body by weight. Nearly three-quarters of this is Ca and P; the rest is mainly Cl, Mg, K, Na, and S. Minerals contribute significantly to body structure. The bones and teeth consist partly of crystals of calcium, phosphate, magnesium, fluoride, and sulfate ions. Many proteins include sulfur, and phosphorus is a major component of nucleic acids, ATP, and cell membranes. Minerals also enable enzymes and other organic molecules to function. Iodine is a component of thyroid hormone; iron is a component of hemoglobin; and some enzymes function only when manganese, zinc, copper, or other minerals are bound to them. The electrolytes needed for nerve and muscle function are mineral salts.

2.1b Atomic Structure

In the fifth century BCE, the Greek philosopher Democritus reasoned that we can cut matter such as a gold nugget into smaller and smaller pieces, but there must ultimately be particles so small that nothing could cut them. He called these imaginary particles **atoms**¹ (“indivisible”). Atoms were only a philosophical concept until 1803, when English chemist John Dalton began to develop an atomic theory based on experimental evidence. In 1913, Danish physicist Niels Bohr proposed a model of atomic structure similar to planets orbiting the sun (**fig. 2.1**). Bohr’s model is a useful schematic for visualizing the constituents of an atom and chemical reactions between them, but it doesn’t represent real atomic structure any more than a student’s ball-and-stick model kit resembles real molecules. According to quantum mechanics, atoms are not spherical; they have no solid surface or boundary; and their subatomic particles have only certain probabilities of being in any given place at any given time (**fig. 2.1c**).

At the center of an atom is the **nucleus**, composed of protons and neutrons. **Protons** (p^+) have a single positive charge and **neutrons** (n^0) have no charge. Each proton or neutron weighs approximately 1 *atomic mass unit* (*amu*). The *atomic mass* of an element is approximately equal to its total number of protons and neutrons.

Around the nucleus are one or more clouds of **electrons** (e^-), tiny particles with a single negative charge and very low mass. It takes 1,836 electrons to equal the mass of one proton, so for most purposes we can disregard their mass. A person who weighs 64 kg (140 lb) contains less than 24 g (1 oz) of electrons. This hardly means that we can ignore electrons, however. They determine the chemical properties of an atom, governing what molecules can exist and what chemical reactions can occur. The number of electrons equals the number of protons, so their charges cancel each other and an atom is electrically neutral.

FIGURE 2.1 Models of Atomic Structure. (a) The Bohr planetary model of carbon, with electrons in two concentric energy levels (shells), the higher-energy electrons farther from the nucleus. (b) The Bohr model of sodium, with a third electron shell. (c) The more realistic quantum mechanical model of carbon, in which electrons are depicted only by their probability of being in a given place at a given time, in shells separated by clear zones (*nodes*) of low to zero probability.

Electrons swarm about the nucleus in concentric regions called **electron shells** (*energy levels*). The more energy an electron has, the farther away from the nucleus its orbit lies. Each shell holds a limited number of electrons. The elements known to date have up to seven electron shells, but those ordinarily involved in human physiology don’t exceed four. Electrons of the outermost shell, called **valence electrons**, determine the chemical bonding properties of an atom. Illustrations of atoms greatly understate the distances between their nuclei and electrons in order to fit the page. If you imagine the nucleus of an atom to be the size of a basketball, its nearest electron would be about 48 km (30 mi.) away.

2.1c Isotopes and Radioactivity

Dalton believed that every atom of an element was identical. We now know, however, that all elements have varieties called **isotopes**,² which differ from one another only in number of neutrons and therefore in atomic mass. Hydrogen atoms, for example, have only one proton. In the most common isotope, symbolized ^1H , that’s all there is to the nucleus. Hydrogen has two other

¹*a* = not; *tom* = cut

²*iso* = same; *top* = place (same position in the periodic table)

DEEPER INSIGHT 2.1

MEDICAL HISTORY

Radiation and Madame Curie

In 1896, French scientist Henri Becquerel (1852–1908) discovered that uranium darkened photographic plates through several thick layers of paper. Marie Curie (1867–1934) and her husband Pierre Curie (1859–1906) discovered that polonium and radium did likewise. Marie coined the term *radioactivity* for the emission of energy by these elements. Becquerel and the Curies shared a Nobel Prize in 1903 for this discovery.

Marie Curie (**fig. 2.2**) was not only the first woman in the world to receive a Nobel Prize, but also the first woman in France to receive a Ph.D. She received a second Nobel Prize in 1911 for further work in radiation. Curie crusaded to train women for careers in science, and in World War I, she and her daughter, Irène Joliot-Curie (1897–1956), trained physicians in the use of X-ray machines. Marie pioneered radiation therapy for breast and uterine cancer.

In the wake of such discoveries, radium was regarded as a wonder drug. Unaware of its danger, people drank radium tonics and flocked to health spas to bathe in radium-enriched waters. Marie herself suffered extensive damage to her hands from handling radioactive minerals and died of radiation poisoning at age 67. The following year, Irène and her husband, Frédéric Joliot (1900–1958), were awarded a Nobel Prize for work in artificial radioactivity and synthetic radioisotopes. Apparently also a martyr to her science, Irène died of leukemia, possibly induced by radiation exposure.

FIGURE 2.2 Marie Curie (1867–1934). This portrait was made in 1911, when Curie received her second Nobel Prize.

Library of Congress Prints and Photographs Division [LC-DIG-ggbain-06354]

FIGURE 2.3 Isotopes of Hydrogen. The three isotopes differ only in the number of neutrons present.

isotopes, however: *deuterium* (^2H) with one proton and one neutron, and *tritium* (^3H) with one proton and two neutrons (**fig. 2.3**). Over 99% of carbon atoms have an atomic mass of 12 ($6\text{p}^+, 6\text{n}^0$) and are called carbon-12 (^{12}C), but a small percentage of carbon atoms are ^{13}C , with seven neutrons, and ^{14}C , with eight. Despite their differences in neutrons, however, all isotopes of a given element behave the same chemically. Deuterium (^2H), for example, reacts with oxygen the same way ^1H does to produce water.

The *atomic weight* (relative atomic mass) of an element accounts for the fact that an element is a mixture of isotopes. If all carbon were ^{12}C , the atomic weight of carbon would be the same as its atomic mass, 12.000. But since a sample of carbon also contains small amounts of the heavier isotopes ^{13}C and ^{14}C , the atomic weight is slightly higher, 12.011.

Although different isotopes of an element exhibit identical chemical behavior, they differ in physical behavior. Many of them are unstable and *decay* (break down) to more stable isotopes by giving off radiation. Unstable isotopes are therefore called **radioisotopes**, and the process of decay is called **radioactivity** (see Deeper Insight 2.1). Every element has at least one radioisotope. Oxygen, for example, has three stable isotopes and five radioisotopes. All of us contain radioisotopes such as ^{14}C and ^{40}K —that is, we are all mildly radioactive!

High-energy radiation, such as that emitted by radioisotopes, ejects electrons from other atoms, converting atoms to ions; thus, it is called **ionizing radiation**. It destroys molecules and produces dangerous free radicals and ions in human tissues. In high doses, ionizing radiation is quickly fatal. In lower doses, it can be *mutagenic* (causing mutations in DNA) and *carcinogenic* (triggering cancer as a result of mutation).

Examples of ionizing radiation include ultraviolet rays, X-rays, and three kinds of radiation produced by nuclear decay: *alpha* (α) *particles*, *beta* (β) *particles*, and *gamma* (γ) *rays*. An alpha particle consists of two protons and two neutrons (equivalent to a helium nucleus), and a beta particle is a free electron. Alpha particles are too large to penetrate the skin, and beta particles penetrate only a few millimeters. They're relatively harmless when emitted by sources outside the body, but very dangerous when emitted by radioisotopes that have gotten into the body. Strontium-90 (^{90}Sr), for example, has been released by nuclear accidents and the atmospheric testing of nuclear weapons

in the 1950s and 1960s. It settles onto pastures and contaminates cow's milk. In the body, it behaves chemically like calcium, becoming incorporated into the bones, where it emits beta particles for years. Uranium and plutonium emit gamma rays. Because of their high penetrating power, these rays are very dangerous even when emitted by sources outside the body.

Each radioisotope has a characteristic **physical half-life**, the time required for 50% of its atoms to decay to a more stable isotope. One gram of ^{90}Sr , for example, would be half gone in 28 years. In 56 years, there would still be 0.25 g left, in 84 years 0.125 g, and so forth. Many radioisotopes are much longer-lived. The half-life of ^{40}K , for example, is 1.3 billion years. Nuclear power plants produce hundreds of radioisotopes that will be intensely radioactive for at least 10,000 years—longer than the life of any disposal container yet conceived.

The **biological half-life** of a radioisotope is the time required for half of it to disappear from the body. Some is lost by radioactive decay and even more by excretion from the body. Cesium-137, for example, has a physical half-life of 30 years but a biological half-life of only 17 days. Chemically, it behaves like potassium; it is quite mobile and rapidly excreted by the kidneys.

There are several ways to measure the intensity of ionizing radiation, the amount absorbed by the body, and its biological effects. To understand the units of measurement requires a grounding in physics beyond the scope of this book, but the standard international (SI) unit of radiation dosage is the *sievert*³ (Sv), which takes into account the type and intensity of radiation and its biological effect. Doses of 5 Sv or more are usually fatal. The average person worldwide receives about 2.4 millisieverts (mSv) per year in *background radiation* from natural sources and another 0.6 mSv from artificial sources. The most significant natural source is *radon*, a gas produced by the decay of uranium in the earth; it can accumulate in buildings to unhealthy levels. Artificial sources of radiation exposure include medical X-rays, CT and PET scans, radiation therapy, and consumer products such as televisions, smoke detectors, and luminous watch dials. A CT scan averages about 10 to 30 mSv for a full-body scan and 10 mSv for an abdominopelvic scan only; a typical mammogram is 0.4 to 0.6 mSv; a chest X-ray is about 0.1 mSv; and a hand or foot X-ray is about 0.001 mSv. Such voluntary exposure must be considered from the standpoint of its risk-to-benefit ratio. The benefits of a smoke detector or mammogram far outweigh the risk from the low levels of radiation involved. Radiation therapists and radiologists face a greater risk than their patients, however, and astronauts and airline flight crews receive more than average exposure. U.S. federal standards set a limit of 50 mSv/year as acceptable occupational exposure to ionizing radiation.

2.1d Ions, Electrolytes, and Free Radicals

Ions are charged particles with unequal numbers of protons and electrons. An ion can consist of a single atom with a positive or negative charge (such as Na^+ or Cl^-); a group of atoms such as

phosphate (PO_4^{3-}) and bicarbonate (HCO_3^-) ions; or a molecule as large as a protein with many charges on it.

Ions form because elements with one to three valence electrons tend to give them up, and those with four to seven electrons tend to gain more. If an atom of the first kind is exposed to an atom of the second, electrons may transfer from one to the other and turn both of them into ions. This process is called *ionization*. The particle that gains electrons acquires a negative charge and is called an **anion** (AN-eye-on). The one that loses electrons acquires a positive charge (because it then has a surplus of protons) and is called a **cation** (CAT-eye-on). This happens, for example, when sodium and chlorine meet (**fig. 2.4**). One electron transfers from sodium to chlorine, producing a sodium ion with a unit positive charge (Na^+) and a chloride ion with a unit negative charge (Cl^-).

Some elements exist in two or more ionized forms. Iron, for example, has ferrous (Fe^{2+}) and ferric (Fe^{3+}) ions. Note that some ions have a single positive or negative charge, whereas others have

FIGURE 2.4 Ionization.

³Rolf Maximillian Sievert (1896–1966), Swedish radiologist

TABLE 2.2

Major Electrolytes and the Ions Released by their Dissociation

Electrolyte (salt)		Cations and Anions
Calcium chloride (CaCl_2)	$\longrightarrow$	$\text{Ca}^{2+} + 2 \text{Cl}^-$
Disodium phosphate (Na_2HPO_4)	$\longrightarrow$	$2 \text{Na}^+ + \text{HPO}_4^{2-}$
Magnesium chloride (MgCl_2)	$\longrightarrow$	$\text{Mg}^{2+} + 2 \text{Cl}^-$
Potassium chloride (KCl)	$\longrightarrow$	$\text{K}^+ + \text{Cl}^-$
Sodium bicarbonate (NaHCO_3)	$\longrightarrow$	$\text{Na}^+ + \text{HCO}_3^-$
Sodium chloride (NaCl)	$\longrightarrow$	$\text{Na}^+ + \text{Cl}^-$

charges of ± 2 or ± 3 because they gain or lose more than one electron. The charge on an ion is called its *valence*.

Ions with opposite charges are attracted to each other and tend to follow each other through the body. Thus, when Na^+ is excreted in the urine, Cl^- tends to follow it. The attraction of cations and anions to each other is especially important in the excitation of muscle and nerve cells, as we shall see in later chapters.

Salts such as sodium chloride (NaCl) and calcium chloride (CaCl_2) are electrically neutral compounds of cations and anions. In most cases relevant to human physiology, they readily dissociate in water into their respective ions, and thus act as electrolytes.

Electrolytes are substances that ionize in water (acids, bases, or salts) and form solutions capable of conducting electricity (table 2.2). We can detect electrical activity of the muscles, heart, and brain with electrodes on the skin because electrolytes in the body fluids conduct electrical currents from these organs to the skin surface. Electrolytes are important for their chemical reactivity (as when calcium phosphate becomes incorporated into bone), osmotic effects (influence on water content and distribution in the body), and electrical effects (which are essential to nerve and muscle function). Electrolyte balance is one of the most important considerations in patient care. Electrolyte imbalances have effects ranging from muscle cramps and brittle bones to coma and cardiac arrest.

Free radicals are unstable, highly reactive chemical particles with an odd number of electrons. For example, oxygen normally exists as a stable molecule composed of two oxygen atoms, O_2 ; but if an additional electron is added, it becomes a free radical called the *superoxide anion*, $\text{O}_2^{\bullet-}$. Free radicals are represented with a dot to symbolize the odd electron.

Free radicals are produced by some normal metabolic reactions of the body (such as the ATP-producing oxidation reactions in mitochondria, and a reaction that some white blood cells use to kill bacteria); by radiation (such as ultraviolet radiation and X-rays); and by chemicals (such as nitrites, used as preservatives in some wine, meat, and other foods). They're short-lived and combine quickly with molecules such as fats, proteins, and DNA, converting them into free radicals and triggering chain reactions that destroy still more molecules. Among the damages caused by free radicals are some forms of cancer and myocardial infarction, the death of heart tissue. One theory of aging is that it results in part from lifelong cellular damage by free radicals.

Because free radicals are so common and destructive, the body has natural mechanisms for neutralizing them. An **antioxidant** is

a chemical that neutralizes free radicals. For example, the body produces an enzyme called *superoxide dismutase (SOD)* that converts superoxide into oxygen and hydrogen peroxide. Selenium, vitamin E (α -tocopherol), vitamin C (ascorbic acid), and carotenoids (such as β -carotene) are some antioxidants obtained from the diet. Dietary deficiencies of antioxidants have been associated with increased risk of heart attacks, sterility, muscular dystrophy, and other disorders.

2.1e Molecules and Chemical Bonds

Molecules are chemical particles composed of two or more atoms united by a chemical bond. The atoms may be identical, as in nitrogen (N_2), or different, as in glucose ($\text{C}_6\text{H}_{12}\text{O}_6$). Molecules composed of two or more elements are called **compounds**. Oxygen (O_2) and carbon dioxide (CO_2) are both molecules, because they consist of at least two atoms; but only CO_2 is a compound, because it has atoms of two different elements.

Molecules are represented by *molecular formulae* that identify their elements and show how many atoms of each are present. Molecules with identical molecular formulae but different arrangements of their atoms are called **isomers**⁴ of each other. For example, both ethanol and ethyl ether have the molecular formula $\text{C}_2\text{H}_6\text{O}$, but they are certainly not interchangeable! To show the difference between them, we use *structural formulae* that show the location of each atom (fig. 2.5).

The **molecular weight (MW)** of a compound is the sum of the atomic weights of its atoms. Rounding to whole numbers, we can calculate the approximate MW of glucose ($\text{C}_6\text{H}_{12}\text{O}_6$), for example:

6 C atoms	×	12 amu each	=	72 amu
12 H atoms	×	1 amu each	=	12 amu
6 O atoms	×	16 amu each	=	96 amu
Molecular weight (MW)				= 180 amu

Molecular weight is needed to compute some measures of concentration discussed later (see section 2.2d and appendix B).

⁴*iso* = same; *mer* = part

	Structural formulae	Condensed structural formulae	Molecular formulae
Ethanol		$\text{CH}_3\text{CH}_2\text{OH}$	$\text{C}_2\text{H}_6\text{O}$
Ethyl ether		CH_3OCH_3	$\text{C}_2\text{H}_6\text{O}$

FIGURE 2.5 Two Structural Isomers—Ethanol and Ethyl Ether. The molecular formulae are identical, but their structures, chemical properties, and physiological effects are different.

TABLE 2.3 Types of Chemical Bonds	
Bond Type	Definition and Remarks
Ionic Bond	Relatively weak attraction between an anion and a cation. Easily disrupted in water, as when salt dissolves.
Covalent Bond	Sharing of one or more pairs of electrons between nuclei.
Single covalent	Sharing of one electron pair.
Double covalent	Sharing of two electron pairs. Often occurs between carbon atoms, between carbon and oxygen, and between carbon and nitrogen.
Nonpolar covalent	Covalent bond in which electrons are equally attracted to both nuclei. May be single or double. Strongest type of chemical bond.
Polar covalent	Covalent bond in which electrons are more attracted to one nucleus than to the other, resulting in slightly positive and negative regions in one molecule. May be single or double.
Hydrogen Bond	Weak attraction between polarized molecules or between polarized regions of the same molecule. Important in the three-dimensional folding and coiling of large molecules such as DNA and proteins. Easily disrupted by temperature and pH changes.
Van der Waals Force	Weak, brief attraction due to random disturbances in the electron clouds of adjacent atoms. Weakest of all bonds individually, but can have strong effects collectively.

A molecule is held together, and molecules are attracted to one another, by forces called **chemical bonds**. The bonds of greatest physiological interest are *ionic bonds*, *covalent bonds*, *hydrogen bonds*, and *van der Waals forces* (table 2.3).

An **ionic bond** is the attraction of a cation to an anion. Sodium (Na^+) and chloride (Cl^-) ions, for example, are attracted to each other and form the compound sodium chloride (NaCl), common table salt. Ionic compounds can be composed of more than two ions, such as calcium chloride, CaCl_2 . Ionic bonds easily dissociate (break up) in the presence of something more attractive, such as water. The ionic bonds of NaCl break down easily as salt dissolves in water, because both Na^+ and Cl^- are more attracted to water molecules than they are to each other.

▶▶▶ **APPLY WHAT YOU KNOW**

Do you think ionic bonds are common in human body fluids? Explain your answer.

Covalent bonds form by the sharing of electrons. For example, two hydrogen atoms share valence electrons to form a hydrogen molecule, H_2 (fig. 2.6a). The two electrons, one donated by each atom, swarm around both nuclei in a dumbbell-shaped cloud. A *single covalent bond* is the sharing of a single pair of electrons. It is symbolized by a single line between atomic symbols, for example, $\text{H}-\text{H}$. A *double covalent bond* is the sharing of two pairs of electrons. In carbon dioxide, for example, a central carbon atom shares two electron pairs with each oxygen atom. Such bonds are symbolized by double lines—for example, $\text{O}=\text{C}=\text{O}$ (fig. 2.6b).

When shared electrons spend approximately equal time around each nucleus, they form a *nonpolar covalent bond* (fig. 2.7a), the strongest of all chemical bonds. Carbon atoms bond to each other with nonpolar covalent bonds. If shared electrons

FIGURE 2.6 Covalent Bonding. (a) Two hydrogen atoms share a single pair of electrons to form a hydrogen molecule. (b) A carbon dioxide molecule, in which a carbon atom shares two pairs of electrons with each oxygen atom, forming double covalent bonds.

spend significantly more time orbiting one nucleus than they do the other, they lend their negative charge to the region where they spend the most time, and they form a *polar covalent bond* (fig. 2.7b). When hydrogen bonds with oxygen, for example, the electrons are more attracted to the oxygen nucleus and orbit it more than they do the hydrogen. This makes the oxygen region

FIGURE 2.7 Nonpolar and Polar Covalent Bonds. (a) A nonpolar covalent bond between two carbon atoms, formed by electrons that spend an equal amount of time around each nucleus, as represented by the symmetric blue cloud. (b) A polar covalent bond, in which electrons orbit one nucleus significantly more than the other, as represented by the asymmetric cloud. This results in a slight negative charge (δ^-) in the region where the electrons spend most of their time, and a slight positive charge (δ^+) at the other pole.

of the molecule slightly negative and the hydrogen region slightly positive. The Greek delta (δ) is used to symbolize a charge less than that of one electron or proton. A slightly negative region of a molecule is represented δ^- and a slightly positive region is represented δ^+ .

A **hydrogen bond** is a weak attraction between a slightly positive hydrogen atom in one molecule and a slightly negative oxygen or nitrogen atom in another. Water molecules, for example, are weakly attracted to each other by hydrogen bonds (**fig. 2.8**). Hydrogen bonds also form between different regions of the same molecule, especially in very large molecules such as proteins and DNA. They cause such molecules to fold or coil into precise three-dimensional shapes. Hydrogen bonds are represented by dotted or broken lines between atoms: $\text{—C=O}\cdots\text{H—N—}$. Hydrogen bonds are relatively weak individually, but they have a strong collective effect and are enormously important to physiology.

Van der Waals⁵ forces are important in protein folding, the binding of proteins to each other and to other molecules such as hormones, and the association of lipid molecules with each other in cell membranes. They're weak, brief attractions between neutral atoms. When electrons orbit a nucleus, they don't maintain a uniform distribution but show random fluctuations in density. If the electrons briefly crowd toward one side of an atom, they render that side slightly negative and the other side slightly positive for

FIGURE 2.8 Hydrogen Bonding of Water. The polar covalent bonds of water molecules enable each oxygen to form a hydrogen bond with a hydrogen of a neighboring molecule. Thus, the water molecules are weakly attracted to each other.

? *Why would this behavior raise the boiling point of water above that of a nonpolar liquid?*

a moment. If another atom is close enough to this one, the second atom responds with disturbances in its own electron cloud. Oppositely charged regions of the two atoms then very briefly attract each other.

A single van der Waals force is only about 1% as strong as a covalent bond, but when two surfaces or large molecules meet, the van der Waals forces between large numbers of atoms can create a very strong attraction. This is how plastic wrap clings to food and dishes and even a heavy lizard, such as a gecko, can walk up a windowpane.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. Consider iron (Fe), hydrogen gas (H_2), and ammonia (NH_3). Which of them is or are atoms? Which of them is or are molecules? Which of them is or are compounds? Explain each answer.
2. Why is the biological half-life of a radioisotope shorter than its physical half-life?
3. Where do free radicals come from? What harm do they do? How is the body protected from free radicals?

⁵Johannes Diderik van der Waals (1837–1923), Dutch physicist

4. How does an ionic bond differ from a covalent bond?
5. What is a hydrogen bond? Why do hydrogen bonds depend on the existence of polar covalent bonds?

2.2 Water and Mixtures

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. define *mixture* and distinguish between mixtures and compounds;
- b. describe the biologically important properties of water;
- c. show how three kinds of mixtures differ from each other;
- d. define *acid* and *base* and interpret the pH scale; and
- e. discuss some ways in which the concentration of a solution can be expressed, and the kinds of information we can derive from the different units of measure.

Our body fluids are complex mixtures of chemicals. A **mixture** consists of substances that are physically blended but not chemically combined; each substance retains its own chemical properties. To contrast a mixture with a compound, consider sodium chloride again. Sodium is a lightweight metal that bursts into flame upon contact with water, and chlorine is a yellow-green poisonous gas that was once used in chemical warfare. When these elements chemically react, they form common table salt. Clearly, the compound has properties much different from the properties of its elements. But if you were to put a little salt on your melon, the melon would taste salty and sweet because the sugar of the melon and the salt you added would merely form a mixture in which each compound retained its individual properties.

2.2a Water

Most mixtures in the body consist of chemicals dissolved or suspended in water. Water constitutes 50% to 75% of one's body weight, depending on age, sex, fat content, and other factors. Its structure, simple as it is, has profound biological effects. Two aspects of its structure are particularly important: (1) Its atoms are joined by polar covalent bonds, and (2) the molecule is V-shaped, with a 105° bond angle (**fig. 2.9a**). This makes the molecule as a whole polar, because there is a slight negative charge (δ^-) on the oxygen at the apex of the V and a slight positive charge (δ^+) on each hydrogen. Like little magnets, water molecules are attracted to one another by hydrogen bonds (**fig. 2.8**). This gives water a set of properties that account for its ability to support life: *solvency*, *cohesion*, *adhesion*, *chemical reactivity*, and *thermal stability*.

Solvency is the ability to dissolve other chemicals. Water is called the *universal solvent* because it dissolves a broader range of substances than any other liquid. Substances that dissolve in water, such as sugar, are said to be **hydrophilic**⁶ (HY-dro-FILL-ic); the relatively few substances that do not, such as fats, are

hydrophobic⁷ (HY-dro-FOE-bic). Virtually all metabolic reactions depend on the solvency of water. Biological molecules must be dissolved in water to move freely, come together, and react. The solvency of water also makes it the body's primary means of transporting substances from place to place.

To be soluble in water, a molecule usually must be polarized or charged so that its charges can interact with those of water. When NaCl is dropped into water, for example, the ionic bonds between Na^+ and Cl^- are overpowered by the attraction of each ion to water molecules. Water molecules form a cluster, or *hydration sphere*, around each sodium ion with the $\text{O}^{\delta-}$ pole of each water molecule facing the sodium ion. They also form a hydration sphere around each chloride ion, with the $\text{H}^{\delta+}$ poles facing it. This isolates the sodium ions from the chloride ions and keeps them dissolved (**fig. 2.9b**).

Adhesion is the tendency of one substance to cling to another, whereas *cohesion* is the tendency of molecules of the same substance to cling to each other. Water adheres to the body's tissues and forms a lubricating film on membranes such as the pleura and pericardium. This reduces friction as the lungs and heart contract and expand and rub against these membranes. Water also is a very cohesive liquid because of its hydrogen bonds. This is why, when you spill water, it forms a puddle and evaporates slowly. By contrast, if you spill a nonpolar substance such as liquid nitrogen, it dances about and evaporates in seconds, like a drop of water in a hot dry skillet. This is because nitrogen molecules have no attraction for each other, so the little bit of heat is enough to disperse them into the air. The cohesion of water is especially evident at its surface, where it forms an elastic layer called the *surface film* held together by a force called *surface tension*. This force causes water to hang in drops from a leaky faucet and travel in sweaty rivulets down one's perspiring skin. Cohesion plays an important role in breathing. When you inhale, the muscles between your ribs pull the chest wall outward, including the parietal pleura lining the rib cage (see atlas A). The wet visceral pleura on the lung surface goes with it because of the cohesion between the water layers of both membranes, and this movement expands the lungs.

The *chemical reactivity* of water is its ability to participate in chemical reactions. Not only does water ionize many other chemicals such as acids and salts, but water itself ionizes into H^+ and OH^- . These ions can be incorporated into other molecules, or released from them, in the course of chemical reactions such as *hydrolysis* and *dehydration synthesis*, described later in this chapter.

The *thermal stability* of water helps to stabilize the internal temperature of the body. It results from the high *heat capacity* of water—the amount of heat required to raise the temperature of 1 g of a substance by 1°C. The base unit of heat is the **calorie**⁸ (**cal**)—1 cal is the amount of heat that raises the temperature of 1 g of water 1°C. The same amount of heat would raise the temperature of a nonpolar substance such as nitrogen about four times as much. The difference stems from the presence or absence of hydrogen bonding. To increase in temperature, the molecules of a substance must move around more actively. The hydrogen bonds of water molecules inhibit their movement, so water can absorb

⁶hydro = water; philic = loving, attracted to

⁷hydro = water; phobic = fearing, avoiding

⁸calor = heat

FIGURE 2.9 Water and Hydration Spheres. (a) A water molecule showing its bond angle and polarity. (b) Water molecules aggregate around a sodium ion with their negatively charged oxygen poles facing the Na^+ and aggregate around a chloride ion with their positively charged hydrogen poles facing the Cl^- .

a given amount of heat without changing temperature (molecular motion) as much.

The high heat capacity of water also makes it a very effective coolant. When it changes from a liquid to a vapor, water carries a large amount of heat with it. One milliliter of perspiration evaporating from the skin removes about 500 cal of heat from the body. This effect is very apparent when you're sweaty and stand in front of a fan or in a cooling breeze.

▶▶▶ APPLY WHAT YOU KNOW

Why are heat and temperature not the same thing?

2.2b Solutions, Colloids, and Suspensions

Mixtures of other substances in water can be classified as *solutions*, *colloids*, and *suspensions*.

A **solution** consists of particles of matter called the **solute** mixed with a more abundant substance (usually water) called the **solvent**. The solute can be a gas, solid, or liquid—as in a solution of oxygen, sodium chloride, or alcohol in water, respectively. Solutions are defined by the following properties:

- The solute particles are under 1 nanometer (nm) in size. The solute and solvent therefore cannot be visually distinguished from each other, even with a microscope.
- Such small particles don't scatter light noticeably, so solutions are usually transparent (**fig. 2.10a**).
- The solute particles can pass through most selectively permeable membranes, such as dialysis tubing and cell membranes.
- The solute doesn't separate from the solvent when the solution is allowed to stand.

The most common **colloids**⁹ in the body are mixtures of protein and water, such as the albumin in blood plasma. Many colloids can change from liquid to gel states—gelatin desserts, agar culture media, and the fluids within and between our cells, for example. Colloids are defined by the following physical properties:

- The colloidal particles range from 1 to 100 nm in size.
- Particles this large scatter light, so colloids are usually cloudy (**fig. 2.10b**).
- The particles are too large to pass through most selectively permeable membranes.
- The particles are still small enough, however, to remain permanently mixed with the solvent when the mixture stands.

The blood cells in our blood plasma exemplify a **suspension**. Suspensions are defined by the following properties:

- The suspended particles exceed 100 nm in size.
- Such large particles render suspensions cloudy or opaque.
- The particles are too large to penetrate selectively permeable membranes.
- The particles are too heavy to remain permanently suspended, so suspensions separate on standing. Blood cells, for example, form a suspension in the blood plasma and settle to the bottom of a tube when blood is allowed to stand without mixing (**fig. 2.10c, d**).

An **emulsion** is a suspension of one liquid in another, such as oil-and-vinegar salad dressing. The fat in breast milk is an emulsion, as are medications such as Kaopectate and milk of magnesia.

⁹*collo* = glue; *oid* = like, resembling

FIGURE 2.10 A Solution, a Colloid, and a Suspension. Top row: Photographs of a representative solution, colloid, and suspension. Bottom row: Symbolic representation of the particle sizes in each mixture. (a) In a copper sulfate solution, the solute particles are so small they remain permanently mixed and the solution is transparent. (b) In milk, the protein molecules are small enough to remain permanently mixed, but large enough to scatter light, so the mixture is opaque. (c) In blood, the red blood cells scatter light and make the mixture opaque. (d) Red blood cells are too large to remain evenly mixed, so they settle to the bottom as in this blood specimen that stood overnight.

Top: Kenneth S. Saladin

A single mixture can fit into more than one of these categories. Blood is a perfect example—it is a solution of sodium chloride, a colloid of protein, and a suspension of cells. Milk is a solution of calcium, a colloid of protein, and an emulsion of fat. **Table 2.4** summarizes the types of mixtures and provides additional examples.

2.2c Acids, Bases, and pH

Most people have some sense of what acids and bases are. Advertisements are full of references to excess stomach acid and pH-balanced shampoo. We know that drain cleaner (a strong base) and battery acid can cause serious chemical burns. But what exactly do “acidic” and “basic” mean, and how can they be quantified?

An **acid** is any *proton donor*, a molecule that releases a proton (H^+) in water. A **base** is a proton acceptor. Since hydroxide ions (OH^-) accept H^+ , many bases are substances that release hydroxide ions—sodium hydroxide (NaOH), for example. A base doesn’t have to be a hydroxide donor, however. Ammonia (NH_3) is also a base. It doesn’t release a hydroxide ion, but it readily accepts a hydrogen ion to become an ammonium ion (NH_4^+).

Acidity is expressed in terms of **pH**, a measure derived from the molarity of H^+ . Molarity (explained in the next section) is represented by square brackets, so H^+ molarity is symbolized $[\text{H}^+]$. pH is the negative logarithm of hydrogen ion molarity—that is, $\text{pH} = -\log [\text{H}^+]$. In pure water, 1 in 10 million molecules ionizes into hydrogen and hydroxide ions: $\text{H}_2\text{O} \rightleftharpoons \text{H}^+ + \text{OH}^-$. (The symbol $\rightleftharpoons$ denotes a reversible chemical reaction.) Pure water has a neutral pH because it contains equal amounts of H^+ and OH^- . Since 1 in 10 million molecules ionize, the molarity of H^+ and the pH of water are

$$\begin{aligned} [\text{H}^+] &= 0.0000001 \text{ molar} = 10^{-7}\text{M}; \\ \log[\text{H}^+] &= -7; \text{ and} \\ \text{pH} &= -\log[\text{H}^+] = 7. \end{aligned}$$

The pH scale (**fig. 2.11**) was invented in 1909 by Danish biochemist and brewer Søren Sørensen to measure the acidity of beer. The scale extends from 0.0 to 14.0. A solution with a pH of 7.0 is **neutral**; solutions with pH below 7 are **acidic**; and solutions with pH above 7 are **basic (alkaline)**. The lower the pH value, the more hydrogen ions a solution has and the more acidic it is. Since the pH scale is logarithmic, a change of one whole number on the scale represents a 10-fold change in H^+ concentration. In other words, a solution with pH 4 is 10 times as acidic as one with pH 5 and 100 times as acidic as one with pH 6.

Slight disturbances of pH can seriously disrupt physiological functions and alter drug actions (see Deeper Insight 2.2), so it is important that the body carefully control its pH. Blood, for example, normally has a pH ranging from 7.35 to 7.45. Deviations from this range cause tremors, fainting, paralysis, or even death. Chemical solutions that resist changes in pH are called **buffers**. Buffers and acid–base balance are considered in detail in chapter 24.

▶▶▶ APPLY WHAT YOU KNOW

A pH of 7.20 is slightly alkaline, yet a blood pH of 7.20 is called acidosis. Why do you think it is called this?

TABLE 2.4 Types of Mixtures

	Solution	Colloid	Suspension
Particle size	<1 nm	1–100 nm	>100 nm
Appearance	Clear	Often cloudy	Cloudy-opaque
Will particles settle out?	No	No	Yes
Will particles pass through a selectively permeable membrane?	Yes	No	No
Examples	Glucose in blood O ₂ in water Saline solutions Sugar in coffee	Proteins in blood Intracellular fluid Milk protein Gelatin	Blood cells Cornstarch in water Fats in blood Kaopectate

2.2d Other Measures of Concentration

Solutions are often described in terms of their concentration—how much solute is present in a given volume of solution. Concentration is expressed in different ways for different purposes, briefly itemized here and more fully explained in appendix B.

- **Weight per volume.** This is the weight of solute (such as grams, g, or milligrams, mg) in a given volume of solution (such as liters, L, or deciliters, dL). For example, a typical serum cholesterol concentration is 200 mg/dL.
- **Percentage.** This is the weight of solute as a percentage of solution volume (weight per volume, w/v) or volume of a liquid as a percentage of total solution volume (volume per volume, v/v). For example, a common intravenous fluid is D5W, which means 5% w/v dextrose in distilled water. Ethanol is often used as a 70% v/v solution.
- **Molarity.** One mole of a chemical is the number of grams equal to its molecular weight, and molarity (M) is a measure of the number of moles of solute per liter of solution. This reflects not merely the weight of solute in the solution, but the number of molecules per volume. It is the number of molecules, not their total weight, that determines the physiological effect of a solution, so molarity is often the most meaningful measure of concentration. Body fluids are usually quantified in millimolar (mM) concentrations, since they are much less than 1 molar.
- **Milliequivalents per liter.** This unit of measure (expressed mEq/L) is used to denote electrolyte concentration; it takes into account not only the millimolar concentration of a solute but the electrical charge on its particles. This is important to processes such as nerve firing, the heartbeat, and muscle contractions, which are driven by electrical phenomena. The mEq/L concentration of electrolytes is critically important in giving intravenous fluids.

FIGURE 2.11 The pH Scale and Approximate pH of Some Familiar Household Substances. The pH is shown within the white circles. H⁺ molarity increases 10-fold for every step down the scale.

DEEPER INSIGHT 2.2

CLINICAL APPLICATION

pH and Drug Action

The pH of the body fluids has a direct bearing on how one reacts to drugs. Depending on pH, drugs such as aspirin, phenobarbital, and penicillin can exist in charged (ionized) or uncharged forms. Whether a drug is charged or not can determine whether it will pass through cell membranes. When aspirin is in the acidic environment of the stomach, for example, it is uncharged and passes easily through the stomach lining into the bloodstream. Here it encounters a basic pH, whereupon it ionizes. In this state, it is unable to pass back through the membrane, so it accumulates in the blood. This effect, called *ion trapping (pH partitioning)*, can be controlled to help clear poisons from the body. The pH of the urine, for example, can be manipulated so that poisons become trapped there and are more rapidly excreted from the body.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

6. What is the difference between a mixture and a compound?
7. What are hydrophilic and hydrophobic substances? Give an example of each.
8. Why would the cohesion and thermal stability of water be less if water did not have polar covalent bonds?
9. How do solutions, colloids, and suspensions differ from each other? Give an example of each in the human body.
10. If solution A had a H^+ concentration of 10^{-8} M, what would be its pH? If solution B had 1,000 times this H^+ concentration, what would be its pH? Would solution A be acidic or basic? What about solution B?
11. What information can we get from the molarity of a solution that we cannot know from its percentage concentration? What do we know from a concentration in mEq/L that we cannot know from molarity alone?

2.3 Energy and Chemical Reactions**Expected Learning Outcomes**

When you have completed this section, you should be able to

- a. define *energy* and *work*, and describe some types of energy;
- b. understand how chemical reactions are symbolized by chemical equations;
- c. list and define the fundamental types of chemical reactions;
- d. identify the factors that govern the speed and direction of a reaction;
- e. define *metabolism* and its two subdivisions; and
- f. define *oxidation* and *reduction*, and relate these to changes in the energy content of a molecule.

2.3a Energy and Work

Energy is the capacity to do work. To do **work** means to move something, whether a muscle or a molecule. Some examples of physiological work are breaking chemical bonds, building molecules, pumping blood, and contracting skeletal muscles. All of the body's activities are forms of work.

Energy is broadly classified as *potential* or *kinetic energy*. *Potential energy* is energy contained in an object because of its position or internal state but that is not doing work at the time. *Kinetic energy* is energy of motion, energy that is doing work. It is observed in musculoskeletal movements, the flow of ions into a cell, and vibration of the eardrum, for example. The water behind a dam has potential energy because of its position. Let the water flow through, and it exhibits kinetic energy that can be tapped for generating electricity. Like water behind a dam, ions concentrated on one side of a cell membrane have potential energy that can be released by opening gates in the membrane. As the ions flow through the gates, their kinetic energy can be tapped to create a nerve signal or make the heart beat.

Within the two broad categories of potential and kinetic energy, several forms of energy are relevant to human physiology. *Chemical energy* is potential energy stored in the bonds of molecules. Chemical reactions release this energy and make it available for physiological work. *Heat* is the kinetic energy of molecular motion. The temperature of a substance is a measure of rate of this motion, and adding heat to a substance increases molecular motion. *Electromagnetic energy* is the kinetic energy of moving quanta ("packets") of radiation called *photons*. The most familiar form of electromagnetic energy is light. *Electrical energy* has both potential and kinetic forms. It is potential energy when charged particles have accumulated at a point such as a battery terminal or on one side of a cell membrane; it becomes kinetic energy when these particles begin to move and create an electrical current—for example, when electrons move through your household wiring or sodium ions move through a cell membrane.

Free energy is the potential energy available in a system to do useful work. In human physiology, the most relevant free energy is the energy stored in the chemical bonds of organic molecules.

2.3b Classes of Chemical Reactions

A **chemical reaction** is a process in which a covalent or ionic bond is formed or broken. The course of a chemical reaction is symbolized by a **chemical equation** that typically shows the *reactants* on the left, the *products* on the right, and an arrow pointing from the reactants to the products. For example, consider this common occurrence: If you open a bottle of wine and let it stand for several days, it turns sour. Wine "turns to vinegar" because oxygen gets into the bottle and reacts with ethanol to produce acetic acid and water. Acetic acid gives the tart flavor to vinegar and spoiled wine. The equation for this reaction is

FIGURE 2.12 Decomposition, Synthesis, and Exchange Reactions. (a) In a decomposition reaction, large molecules are broken down into simpler ones. (b) In a synthesis reaction, smaller molecules are joined to form larger ones. (c) In an exchange reaction, two molecules exchange atoms.

? To which of these categories does the digestion of food belong?

Ethanol and oxygen are the reactants, and acetic acid and water are the products of this reaction. Not all reactions are shown with the arrow pointing from left to right. In complex biochemical equations, reaction chains are often written vertically, diagonally, or even in circles.

Chemical reactions can be classified as *decomposition*, *synthesis*, or *exchange reactions*. In **decomposition reactions**, a large molecule breaks down into two or more smaller ones (**fig. 2.12a**); symbolically, $AB \rightarrow A + B$. When you eat a potato, for example, digestive enzymes decompose its starch into thousands of glucose molecules, and most cells further decompose glucose to water and carbon dioxide. Starch, a very large molecule, ultimately yields about 36,000 molecules of H_2O and CO_2 .

Synthesis reactions are just the opposite—two or more small molecules combine to form a larger one; symbolically, $A + B \rightarrow AB$ (**fig. 2.12b**). When the body synthesizes proteins, for example, it combines 50 or more amino acids into one protein molecule.

In **exchange reactions**, two molecules exchange atoms or groups of atoms; $AB + CD \rightarrow AC + BD$ (**fig. 2.12c**). For example, when stomach acid (HCl) enters the small intestine, the pancreas secretes sodium bicarbonate ($NaHCO_3$) to neutralize it. The reaction between the two is

We could say the sodium atom has exchanged its bicarbonate group ($-HCO_3$) for a chlorine atom.

Reversible reactions can go in either direction under different circumstances. For example, carbon dioxide combines with water to produce carbonic acid, which in turn decomposes into bicarbonate ions and hydrogen ions:

This reaction appears in this book more often than any other, especially as we later discuss respiratory, urinary, and digestive physiology.

The direction in which a reversible reaction goes is determined by the relative abundance of substances on each side of the equation. If there is a surplus of CO_2 , the foregoing reaction proceeds left to right and produces bicarbonate and hydrogen ions. If bicarbonate and hydrogen ions are present in excess, the reaction proceeds right to left and generates CO_2 and H_2O . Reversible reactions follow the **law of mass action**: They proceed from the reactants in greater quantity to the substances with the lesser quantity. This law will help to explain processes discussed in later chapters, such as why hemoglobin binds oxygen in the lungs yet releases it to muscle tissue.

In the absence of upsetting influences, reversible reactions exist in a state of **equilibrium**, in which the ratio of products to reactants is stable. The carbonic acid reaction, for example, normally maintains a 20:1 ratio of bicarbonate ions to carbonic acid molecules. This equilibrium can be upset, however, by a surplus of hydrogen ions, which drives the reaction to the left, or adding carbon dioxide and driving it to the right.

2.3c Reaction Rates

Chemical reactions are based on molecular motion and collisions. All molecules are in constant motion, and reactions occur when mutually reactive molecules collide with sufficient force and the right orientation. The rate of a reaction depends on the nature of the reactants and on the frequency and force of these collisions. Some factors that affect reaction rates are

- **Concentration.** Reaction rate increases when the reactants are more concentrated. This is because the molecules are more crowded and collide more frequently.
- **Temperature.** Reaction rate increases as the temperature rises. This is because heat causes molecules to move more rapidly and collide with greater force and frequency.
- **Catalysts** (CAT-uh-lists). These are substances that temporarily bind to reactants, hold them in a favorable position to react with each other, and may change the shapes of reactants in ways that make them more likely to react. By reducing the element of chance in molecular collisions, a catalyst speeds up a reaction. It then releases the products and is available to repeat the process with more reactants. The catalyst itself is not consumed or changed by the reaction. The most important biological catalysts are enzymes, discussed later in this chapter.

2.3d Metabolism, Oxidation, and Reduction

All the chemical reactions in the body are collectively called **metabolism**. Metabolism has two divisions: *catabolism* and *anabolism*. **Catabolism**¹⁰ (ca-TAB-oh-lizm) consists of energy-releasing decomposition reactions. Such reactions break covalent bonds, produce smaller molecules from larger ones, and release energy that can be used for other physiological work. Energy-releasing reactions are called *exergonic*¹¹ reactions. If you hold a beaker of water in your hand and pour sulfuric acid into it, for example, the beaker will get so hot you may have to put it down. If you break down

energy-storage molecules to run a race, you too will get hot. In both cases, the heat signifies that exergonic reactions are occurring.

Anabolism¹² (ah-NAB-oh-lizm) consists of energy-storing synthesis reactions, such as the production of protein or fat. Reactions that require an energy input, such as these, are called *endergonic*¹³ reactions. Anabolism is driven by the energy that catabolism releases, so endergonic and exergonic processes, anabolism and catabolism, are inseparably linked.

Oxidation is any chemical reaction in which a molecule gives up electrons and releases energy. A molecule is *oxidized* by this process, and whatever molecule takes the electrons from it is an *oxidizing agent (electron acceptor)*. The term *oxidation* stems from the fact that oxygen is often involved as the electron acceptor. Thus, we can sometimes recognize an oxidation reaction from the fact that oxygen has been added to a molecule. The rusting of iron, for example, is a slow oxidation process in which oxygen is added to iron to form iron oxide (Fe₂O₃). Many oxidation reactions, however, don't involve oxygen at all. For example, when yeast ferments glucose to ethanol, no oxygen is required; indeed, the ethanol *contains less oxygen* than the glucose originally did, but it is *more oxidized* than the glucose:

Reduction is a chemical reaction in which a molecule gains electrons and energy. When a molecule accepts electrons, it is said to be *reduced*; a molecule that donates electrons to another is therefore called a *reducing agent (electron donor)*. The oxidation of one molecule is always accompanied by the reduction of another, so these electron transfers are known as *oxidation–reduction (redox) reactions*.

It isn't necessary that *only* electrons be transferred in a redox reaction. Often, the electrons are transferred in the form of hydrogen atoms. The fact that a proton (the hydrogen nucleus) is also transferred is immaterial to whether we consider a reaction oxidation or reduction.

¹⁰cato = down, to break down
¹¹ex, exo = out; erg = work

¹²ana = up, to build up
¹³end, endo = in; erg = work

TABLE 2.5 Energy-Transfer Reactions in the Human Body	
Exergonic Reactions	Reactions in which there is a net release of energy. The products have less total free energy than the reactants did.
Oxidation	An exergonic reaction in which electrons are removed from a reactant. Electrons may be removed one or two at a time and may be removed in the form of hydrogen atoms (H or H ₂). The product is then said to be oxidized.
Decomposition	A reaction such as digestion and cell respiration, in which larger molecules are broken down into smaller ones.
Catabolism	The sum of all decomposition reactions in the body.
Endergonic Reactions	Reactions in which there is a net input of energy. The products have more total free energy than the reactants did.
Reduction	An endergonic reaction in which electrons are donated to a reactant. The product is then said to be reduced.
Synthesis	A reaction such as protein and glycogen synthesis, in which two or more smaller molecules are combined into a larger one.
Anabolism	The sum of all synthesis reactions in the body.

We can symbolize oxidation and reduction as follows, letting A and B symbolize arbitrary molecules and letting e^- represent one or more electrons that transfer from molecule A to molecule B:

Ae^- is a reducing agent because it reduces B, and B is an oxidizing agent because it oxidizes Ae^- .

Table 2.5 summarizes these energy-transfer reactions.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

12. Define *energy*. Distinguish potential energy from kinetic energy.
13. Define *metabolism*, *catabolism*, and *anabolism*.
14. What does *oxidation* mean? What does *reduction* mean? Which of them is endergonic and which is exergonic?
15. When sodium chloride forms, which element—sodium or chlorine—is oxidized? Which one is reduced?

2.4 Organic Compounds

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain why carbon is especially well suited to serve as the structural foundation of many biological molecules;
- b. identify some common functional groups of organic molecules from their formulae;
- c. discuss the relevance of polymers to biology and explain how they are formed and broken by dehydration synthesis and hydrolysis;
- d. discuss the types and functions of carbohydrates;
- e. discuss the types and functions of lipids;
- f. discuss protein structure and function;
- g. explain how enzymes function;
- h. describe the structure, production, and function of ATP;
- i. identify other nucleotide types and their functions; and
- j. identify the principal types of nucleic acids.

2.4a Carbon Compounds and Functional Groups

Organic chemistry is the study of compounds of carbon. By 1900, biochemists had classified the large organic molecules of life into four primary categories: *carbohydrates*, *lipids*, *proteins*, and *nucleic acids*. We examine the first three in this chapter but describe the details of nucleic acids, which are concerned with genetics, in chapter 4.

Carbon is an especially versatile atom that serves as the basis of a wide variety of structures. It has four valence electrons, so it bonds covalently with other atoms that share four more to complete its valence shell. Carbon atoms readily bond with each other and can form long chains, branched molecules, and rings—an enormous variety of **carbon backbones** for organic molecules. Carbon also commonly forms covalent bonds with hydrogen, oxygen, nitrogen, and sulfur.

Carbon backbones carry a variety of **functional groups**—small clusters of atoms that determine many of the properties of an organic molecule. For example, organic acids bear a **carboxyl group** (car-BOC-sil), and ATP is named for its three **phosphate groups**. Other common functional groups include **hydroxyl**, **methyl**, and **amino groups** (fig. 2.13).

2.4b Monomers and Polymers

Since carbon can form long chains, some organic molecules are gigantic *macromolecules* with molecular weights that range

Name and Symbol	Structure	Occurs in
Hydroxyl (—OH)		Sugars, alcohols
Methyl (—CH ₃)		Fats, oils, steroids, amino acids
Carboxyl (—COOH)		Amino acids, sugars, proteins
Amino (—NH ₂)		Amino acids, proteins
Phosphate (—H ₂ PO ₄)		Nucleic acids, ATP

FIGURE 2.13 Functional Groups of Organic Molecules.

FIGURE 2.14 Dehydration Synthesis and Hydrolysis Reactions. (a) Dehydration synthesis, creating a new covalent bond between two monomers and producing water as a by-product. (b) Hydrolysis, consuming a water molecule to break a covalent bond.

from the thousands (as in starch and proteins) to the millions (as in DNA). Most macromolecules are **polymers**¹⁴—molecules made of a repetitive series of identical or similar subunits called **monomers**. Starch, for example, is a polymer of about 3,000 glucose monomers. In starch, the monomers are identical, whereas in other polymers, the monomers have a basic structural similarity but differ in detail. DNA, for example, is made of 4 kinds of monomers (nucleotides), and proteins are made of 20 kinds (amino acids).

The joining of monomers to form a polymer is called **polymerization**. Living cells achieve this by means of a reaction called **dehydration synthesis (condensation)** (fig. 2.14a). An enzyme removes a hydroxyl group (—OH) from one monomer and a hydrogen (—H) from another, producing water as a by-product. The two monomers become joined by a covalent bond, forming a **dimer**. This is repeated for each monomer added to the chain, potentially leading to a chain long enough to be considered a polymer.

The opposite of dehydration synthesis is **hydrolysis**¹⁵ (fig. 2.14b). In hydrolysis, a water molecule ionizes into OH^- and H^+ . An enzyme breaks the covalent bond linking one monomer to another, and adds OH^- to one monomer and H^+ to the other one. All chemical digestion consists of hydrolysis reactions.

2.4c Carbohydrates

A **carbohydrate**¹⁶ is a hydrophilic organic molecule with the general formula $(\text{CH}_2\text{O})_n$, where n represents the number of carbon atoms. In glucose, for example, $n = 6$ and the formula is $\text{C}_6\text{H}_{12}\text{O}_6$. As the generic formula shows, carbohydrates have a 2:1 ratio of hydrogen to oxygen.

▶▶▶ APPLY WHAT YOU KNOW

Why is carbohydrate an appropriate name for this class of compounds? Relate this name to the general formula of carbohydrates.

The names of individual carbohydrates are often built on the word root *sacchar-* or the suffix *-ose*, both of which mean “sugar” or “sweet.” The most familiar carbohydrates are sugars and starches.

The simplest carbohydrates are monomers called **monosaccharides**¹⁷ (MON-oh-SAC-uh-rides), or simple sugars. The three of primary importance are **glucose**, **galactose**, and **fructose**, all with the molecular formula $\text{C}_6\text{H}_{12}\text{O}_6$; they are isomers of each other (fig. 2.15). We obtain these sugars mainly by the digestion of more complex carbohydrates. Glucose is the “blood sugar” that provides energy to most of our cells. Two other monosaccharides, ribose and deoxyribose, are important components of RNA and DNA, respectively.

Disaccharides are sugars composed of two monosaccharides. The three disaccharides of greatest importance are **sucrose** (made of glucose + fructose), **lactose** (glucose + galactose), and **maltose** (glucose + glucose) (fig. 2.16). Sucrose is produced by sugar-cane and sugar beets and used as common table sugar. Lactose is milk sugar. Maltose is a product of starch digestion and is present in a few foods such as malt beverages and germinating grains.

Short chains of three or more monosaccharides are called **oligosaccharides**¹⁸, and long chains (up to thousands of monosaccharides long) are called **polysaccharides**. There is no exact criterion for when a chain is long enough to be called a polysaccharide, but a chain of 10 or 20 monosaccharides is generally considered an oligosaccharide, whereas a chain of 50 or more is generally considered a polysaccharide. Polysaccharides can be thousands of sugars long and may have molecular weights of 500,000 or more

¹⁴*poly* = many; *mer* = part

¹⁵*hydro* = water; *lysis* = splitting apart

¹⁶*carbo* = carbon; *hydr* = water

¹⁷*mono* = one; *sacchar* = sugar

¹⁸*oligo* = few; *sacchar* = sugars

FIGURE 2.15 The Three Major Monosaccharides. Glucose, galactose, and fructose all have the molecular formula $C_6H_{12}O_6$, but with the atoms arranged differently as shown. Each angle in the rings represents a carbon atom except the one where oxygen is shown. This is a conventional way of representing carbon in the structural formulae of organic compounds.

(compared with 180 for a single glucose). Three polysaccharides of interest to human physiology are glycogen, starch, and cellulose—all composed solely of glucose. Animals, including ourselves, make glycogen, whereas starch and cellulose are plant products.

Glycogen¹⁹ is an energy-storage polysaccharide made by cells of the liver, muscles, brain, uterus, and vagina. It is a long, branched, glucose polymer (fig. 2.17). The liver produces glycogen after a meal, when the blood glucose level is high, and then breaks it down between meals to maintain blood glucose levels when there is no food intake. Muscle stores glycogen for its own energy needs, and the uterus uses it in early pregnancy to nourish the embryo.

Starch is the corresponding energy-storage polysaccharide of plants. They store it when sunlight and nutrients are available and draw from it when photosynthesis is not possible (for example, at night and in winter, when a plant has shed its leaves). Starch is the only significant digestible polysaccharide in the human diet.

Cellulose is a structural polysaccharide that gives strength to the cell walls of plants. It is the principal component of wood,

FIGURE 2.16 The Three Major Disaccharides. Sucrose, lactose, and maltose all consist of two monosaccharides joined through an oxygen atom.

cotton, and paper. It is composed of a chain of a few thousand glucose monomers. Cellulose is the most abundant organic compound on earth and it is a common component of the diets of humans and other animals—yet we have no enzymes to digest it. Nevertheless, it is important as dietary fiber (“bulk” or “roughage”). It swells with water in the digestive tract and helps move other materials through the intestine. We get some nutritional benefit from the breakdown products of bacterial action on cellulose in the large intestine.

Carbohydrates are, above all, a source of energy that can be quickly mobilized. All digested carbohydrate is ultimately converted to glucose, and glucose is oxidized to make ATP, a high-energy compound discussed later. But carbohydrates have other functions as well (table 2.6). They are often **conjugated**²⁰ with (covalently bound to) proteins and lipids. Many lipid and protein molecules at the external surface of the cell membrane have chains of up to 12 sugars attached to them, thus forming **glycolipids** and **glycoproteins**, respectively. Among other functions, glycoproteins are a major component of mucus, which traps particles in the respiratory system, resists infection, and protects the digestive tract from its own acid and enzymes.

¹⁹glyco = sugar; gen = producing

²⁰con = together; jug = join

FIGURE 2.17 Glycogen. This is the only polysaccharide found in human tissues. (a) Part of a glycogen molecule showing the chain of glucose monomers and branching pattern. (b) Detail of the molecule at a branch point.

Proteoglycans are macromolecules in which the carbohydrate component is dominant and a peptide or protein forms a smaller component. Proteoglycans form gels that hold cells and tissues together, form a gelatinous filler in the umbilical cord and eye, lubricate the joints of the skeletal system, and account for the tough rubbery texture of cartilage.

When discussing conjugated macromolecules, it is convenient to refer to each chemically different component as a

moiety²¹ (MOY-eh-tee). Proteoglycans have a protein moiety and a carbohydrate moiety, for example.

2.4d Lipids

A **lipid** is a hydrophobic organic molecule, usually composed only of carbon, hydrogen, and oxygen, with a high ratio of hydrogen to oxygen. A fat called *tristearin* (tri-STEE-uh-rin), for example, has the molecular formula $C_{57}H_{110}O_6$ —more than 18 hydrogens for every oxygen. Lipids are less oxidized than carbohydrates, and thus have more calories per gram. Beyond these criteria, it is difficult to generalize about lipids; they are much more variable in structure than the other macromolecules we are considering. We consider here the five primary types of lipids in humans—*fatty acids*, *triglycerides*, *phospholipids*, *eicosanoids*, and *steroids* (**table 2.7**).

²¹moiety = half

TABLE 2.6 Carbohydrate Functions	
Type	Function
Monosaccharides	
Glucose	Blood sugar—energy source for most cells
Galactose	Converted to glucose and metabolized
Fructose	Converted to glucose and metabolized
Disaccharides	
Sucrose	Cane sugar—digested to glucose and fructose
Lactose	Milk sugar—digested to glucose and galactose; important in infant nutrition
Maltose	Malt sugar—product of starch digestion, further digested to glucose
Polysaccharides	
Cellulose	Structural polysaccharide of plants; dietary fiber
Starch	Energy storage in plant cells; energy source in human diet
Glycogen	Energy storage in animal cells (liver, muscle, brain, uterus, vagina)
Conjugated Carbohydrates	
Glycoprotein	Component of the cell surface coat and mucus, among other roles
Glycolipid	Component of the cell surface coat
Proteoglycan	Cell adhesion; lubrication; supportive filler of some tissues and organs

TABLE 2.7 Lipid Functions	
Type	Function
Bile acids	Steroids that aid in fat digestion and nutrient absorption
Cholesterol	Component of cell membranes; precursor of other steroids
Eicosanoids	Chemical messengers between cells
Fat-soluble vitamins (A, D, E, and K)	Involved in a variety of functions including blood clotting, wound healing, vision, and calcium absorption
Fatty acids	Precursor of triglycerides; source of energy
Phospholipids	Major component of cell membranes; aid in fat digestion
Steroid hormones	Chemical messengers between cells
Triglycerides	Energy storage; thermal insulation; filling space; binding organs together; cushioning organs

FIGURE 2.18 Triglyceride (Fat) Synthesis. The three fatty acids above the arrow (a) combine with glycerol (left) to produce the triglyceride (fat) below the arrow (b). Note the difference between saturated and unsaturated fatty acids and the production of 3 H_2O as a by-product of this dehydration synthesis reaction.

A **fatty acid** is a chain of usually 4 to 24 carbon atoms with a carboxyl group at one end and a methyl group at the other. Fatty acids and the fats made from them are classified as *saturated* or *unsaturated*. A **saturated fatty acid** such as palmitic acid has as much hydrogen as it can carry. No more could be added without exceeding four covalent bonds per carbon; thus, it is “saturated” with hydrogen. In **unsaturated fatty acids** such as linoleic acid, however,

some carbon atoms are joined by double covalent bonds (**fig. 2.18a**). Each of these could potentially share one pair of electrons with another hydrogen atom instead of the adjacent carbon, so hydrogen could be added to this molecule. **Polyunsaturated fatty acids** are those with multiple $\text{C}=\text{C}$ bonds. Most fatty acids can be synthesized by the human body, but a few, called **essential fatty acids**, must be obtained from the diet because we cannot synthesize them.

A **triglyceride** (try-GLISS-ur-ide) is a molecule consisting of a three-carbon alcohol called **glycerol** linked to three fatty acids; triglycerides are more correctly, although less widely, also known as *triacylglycerols*. Each bond between a fatty acid and glycerol is formed by dehydration synthesis (**fig. 2.18b**). Once joined to glycerol, a fatty acid can no longer donate a proton to solution and is therefore no longer an acid. For this reason, triglycerides are also called **neutral fats**. Triglycerides are broken down by hydrolysis reactions, which split each of these bonds apart by the addition of water.

Triglycerides that are liquid at room temperature are also called *oils*, but the difference between a fat and an oil is fairly arbitrary. Coconut oil, for example, is solid at room temperature.

DEEPER INSIGHT 2.3

CLINICAL APPLICATION

Trans Fats and Cardiovascular Health

Trans fats have been a significant part of the American diet for more than a century. Yet in 2015, the U.S. Food and Drug Administration (FDA) ordered food manufacturers to stop using them. So what are *trans* fats, why were they so popular for so long, and why are they now almost entirely banished?

A *trans* fat is a triglyceride containing one or more *trans*-fatty acids. In such fatty acids, there is at least one unsaturated C=C double bond. On each side of that bond, the single covalent C—C bonds angle in opposite directions (*trans* means “across from”) like a pair of bicycle pedals (see arrows in **fig. 2.19a**). This is in contrast to *cis*-fatty acids, in which the two C—C bonds adjacent to the C=C bond angle in the same direction (*cis* means “on the same side”). As you can see (**fig. 2.19b**), the *cis* configuration creates a kink in the chain, whereas the *trans* configuration results in a relatively straight chain. The kink prevents triglycerides with *cis* bonds from packing closely together; hence they are oils. *Trans* fats, however, are more densely packed and therefore solid at room temperature.

Small amounts of *trans* fat occur naturally in meat and dairy products, but in 1911, a food manufacturer invented a method for forcing hydrogen through liquid vegetable oils and converting liquid *cis*-fatty acids to solid *trans*-fatty acids. The resulting *partially hydrogenated oil* (PHO), sold as vegetable shortening, had several advantages and was heavily marketed for household and industrial use. It was easier to use in making such baked goods as pie crusts and biscuits, and it gave products a desirable texture and longer shelf life. To those who avoid pork products, such as vegans, Jews, and Muslims, it was more acceptable than animal fat such as lard. *Trans* fats came to be abundantly used not only by home cooks but also in snack foods, baked goods, frosting, coffee creamer, margarine, and fast foods such as french fries and take-out fried chicken.

But *trans* fats resist enzymatic breakdown in the human body, remain in circulation longer, and have more tendency to deposit in the arteries than saturated and *cis* fats do. Therefore, they raise the risk of coronary artery disease (CAD). A study of more than 80,000 nurses who tracked their diets from 1980 to 1994 showed, among other things, that for every 2% increase in calories from *trans* fats as compared to carbohydrates, the women had a 93% elevated incidence of CAD. As the dangers of *trans* fats became widely known, their consumption in the United States declined greatly after 2003 and they were banned in some cities and states, until the FDA concluded in 2015 that they are “not safe for human consumption” and must be eliminated from processed and restaurant foods.

Animal fats are usually made of saturated fatty acids, so they are called *saturated fats*. They are solid at room or body temperature. Most plant triglycerides are *polyunsaturated fats*, which generally remain liquid at room temperature. Examples include peanut, olive, corn, and linseed oils. Saturated fats contribute more to cardiovascular disease than unsaturated fats, and for this reason it's healthier to cook with vegetable oils than with lard, bacon fat, or butter (but see Deeper Insight 2.3).

The primary function of fat is energy storage, but when concentrated in *adipose tissue*, it also provides thermal insulation and acts as a shock-absorbing cushion for vital organs.

Phospholipids are similar to neutral fats except that in place of one fatty acid, they have a phosphate group which, in turn, is

(a) A *trans*-fatty acid (elaidic acid)

(b) A *cis*-fatty acid (oleic acid)

FIGURE 2.19 Trans- and Cis-Fatty Acids. Each example is unsaturated at the C=C double bond in red. (a) In a *trans*-fatty acid, the bonds on opposite sides of the C=C bond angle in opposite directions (arrows). (b) In a *cis*-fatty acid, the bonds on opposite sides of the C=C bond angle in the same direction. The straight-chain *trans*-fatty acids pack more tightly together, thus remain solid (greasy) at room temperature. Oleic acid melts at 13.5°C (56.3°F), whereas elaidic acid melts at 46.5°C (115.7°F) and therefore doesn't liquify in the human body.

FIGURE 2.20 Lecithin, a Representative Phospholipid. (a) Structural formula. (b) A space-filling model that gives some idea of the actual shape of the molecule. (c) A simplified representation of the phospholipid molecule used in diagrams of cell membranes.

linked to other functional groups. Lecithin is a common phospholipid in which the phosphate is bonded to a nitrogenous group called *choline* (CO-leen) (**fig. 2.20**). Phospholipids have a dual nature. The two fatty acid “tails” of the molecule are hydrophobic, but the phosphate “head” is hydrophilic. Thus, phospholipids are said to be **amphipathic**²² (AM-fih-PATH-ic). Together, the head and the two tails of a phospholipid give it a shape like a clothespin. The most important function of phospholipids is to serve as the structural foundation of cell membranes.

Eicosanoids²³ (eye-CO-sah-noyds) are 20-carbon compounds derived from a fatty acid called *arachidonic acid* (ah-RACK-ih-DON-ic). They function primarily as hormonelike chemical signals between cells. The most functionally diverse eicosanoids are **prostaglandins**, in which five of the carbon atoms are arranged in a ring (**fig. 2.21**). These were originally found in the secretions of bovine prostate glands—hence their name—but they are now known to be produced in almost all tissues. They play a variety of signaling roles in inflammation, blood clotting, hormone action, labor contractions, control of blood vessel diameter, and other processes.

A **steroid** is a lipid with 17 of its carbon atoms arranged in four rings (**fig. 2.22**). **Cholesterol** is the “parent” steroid from

FIGURE 2.21 Prostaglandin. This is a modified fatty acid with five of its carbon atoms arranged in a ring.

FIGURE 2.22 Cholesterol. All steroids have this basic four-ringed structure, with variations in the functional groups and locations of double bonds within the rings.

²²*amphi* = both; *pathic* = feeling

²³*eicosa* = 20

DEEPER INSIGHT 2.4

CLINICAL APPLICATION

“Good” and “Bad” Cholesterol

There is only one kind of cholesterol, and it does far more good than harm. When the popular media refer to “good” and “bad” cholesterol, they are actually referring to droplets in the blood called *lipoproteins*, which are a complex of cholesterol, fat, phospholipids, and protein (see fig. 26.3a). So-called bad cholesterol refers to low-density lipoprotein (LDL), which has a high ratio of lipid to protein and contributes to cardiovascular disease. So-called good cholesterol refers to high-density lipoprotein (HDL), which has a lower ratio of lipid to protein and may help to prevent cardiovascular disease.

Even when food products are advertised as cholesterol-free, they may be high in saturated fat, which stimulates the body to produce more cholesterol. Palmitic acid seems to be the greatest culprit in stimulating elevated cholesterol levels, while linoleic acid has a cholesterol-lowering effect. Both are shown in figure 2.18. Cardiovascular disease is further discussed in Deeper Insight 19.4, and LDLs and HDLs are more fully explained in chapter 26.

which the other steroids are synthesized. The others include cortisol, progesterone, estrogens, testosterone, and bile acids. These differ from each other in the location of C=C bonds within the rings and in the functional groups attached to the rings.

We obtain dietary cholesterol only from foods of animal origin; plants make only trace amounts of no dietary importance. The average adult contains over 200 g (half a pound) of cholesterol. Cholesterol has a bad reputation as a factor in cardiovascular disease (see Deeper Insight 2.4), and it is true that hereditary and dietary factors can elevate blood cholesterol to dangerously high levels. Nevertheless, cholesterol is a natural product of the body and is necessary for human health. In addition to being the precursor of other steroids, it is an important component of cell membranes and is required for proper nervous system function. Only about 15% of our cholesterol comes from the diet; the other 85% is internally synthesized, primarily by the liver.

The principal lipids and their functions are summarized in table 2.7.

2.4e Proteins

The word *protein* is derived from the Greek word *proteios*, meaning “of first importance.” Proteins are the most versatile molecules in the body, and many discussions in this book will draw on your understanding of protein structure and behavior.

Amino Acids and Peptides

A **protein** is a polymer of **amino acids**. An amino acid has a central carbon atom with an amino ($-\text{NH}_2$) and a carboxyl ($-\text{COOH}$) group bound to it (fig. 2.23a). The 20 amino acids used to make proteins are identical except for a third functional group called the *R (radical) group* attached to the central carbon. In the simplest amino acid, glycine, R is merely a hydrogen atom, whereas in the

largest amino acids it includes rings of carbon. Some R groups are hydrophilic and some are hydrophobic. Being composed of many amino acids, proteins as a whole are therefore often amphipathic. The 20 amino acids involved in proteins are shown in appendix D along with their standard abbreviations.

A **peptide** is any molecule composed of two or more amino acids joined by **peptide bonds**. A peptide bond, formed by dehydration synthesis, joins the amino group of one amino acid to the carboxyl group of the next (fig. 2.23b). Peptides are named for the number of amino acids they have—for example, dipeptides

FIGURE 2.23 Amino Acids and Peptides. (a) Four representative amino acids and their symbols. Note that they differ only in the R group, shaded in pink. For structures of all 20 amino acids, see appendix D. (b) The joining of two amino acids by a peptide bond, forming a dipeptide. Side groups R_1 and R_2 could be the groups indicated in pink in part (a), among other possibilities.

are slender filaments better suited for such roles as muscle contraction and providing strength to skin, hair, and tendons.

The amino acid cysteine (Cys), whose R group is $\text{—CH}_2\text{—SH}$ (see fig. 2.23a), often stabilizes a protein's tertiary structure by forming covalent **disulfide bridges**. When two cysteines align with each other, each can release a hydrogen atom, leaving the sulfur atoms to form a disulfide bridge (—S—S—). Disulfide bridges hold separate polypeptide chains together in such molecules as antibodies and insulin (fig. 2.25).

Quaternary²⁵ structure (QUA-tur-nare-ee) is the association of two or more polypeptide chains by noncovalent forces such as ionic bonds and hydrophilic–hydrophobic interactions. It occurs in only some proteins. Hemoglobin, for example, consists of four polypeptides: two identical alpha chains and two identical, slightly longer beta chains (fig. 2.24d).

One of the most important properties of proteins is their ability to change shape, especially tertiary structure. This can be triggered by such influences as voltage changes on a cell membrane during the action of nerve cells, the binding of a hormone to a protein, or the dissociation of a molecule from a protein. Subtle, reversible changes in conformation are important to processes such as enzyme function, muscle contraction, and the opening and closing of pores in cell membranes. **Denaturation** is a more drastic conformational change in response to conditions such as extreme heat or pH. It is seen, for example, when you cook an egg and the egg white (albumen) turns from clear and runny to opaque and stiff. Denaturation makes a protein unable to perform its normal function. It is sometimes reversible, but usually it permanently destroys protein function.

Conjugated proteins have a non-amino acid moiety called a **prosthetic²⁶ group** covalently bound to them. Hemoglobin, for example, not only has the four polypeptide chains described earlier, but each chain also has a complex iron-containing ring called a *heme* moiety attached to it (fig. 2.24d). Hemoglobin cannot transport oxygen unless this group is present. In glycoproteins, as described earlier, the carbohydrate moiety is a prosthetic group.

Protein Functions

Proteins have more diverse functions than other macromolecules. These include

- **Structure.** *Keratin*, a tough structural protein, gives strength to the nails, hair, and skin surface. Deeper layers of the skin, as well as bones, cartilage, and teeth, contain an abundance of the durable protein *collagen*.
- **Communication.** Some hormones and other cell-to-cell signals are proteins, as are the receptors to which the signal molecules bind in the receiving cell. Insulin, for example, is a protein hormone that binds to another protein, its receptor, on the cell surface. Any hormone or other molecule that reversibly binds to a protein is called a **ligand²⁷** (LIG-and).

- **Membrane transport.** Some proteins form *channels* in cell membranes that govern what passes through the membranes and when. Others act as *carriers* that briefly bind to solute particles and transport them to the other side of the membrane. One such protein, for example, is the sodium–potassium pump, which continually pumps sodium ions out of a cell and potassium ions in, maintaining the excitability of nerve and muscle cells.
- **Catalysis.** Most metabolic pathways of the body are controlled by enzymes, which are globular proteins that function as catalysts. Other examples are the digestive enzymes that break food down into absorbable nutrients.
- **Recognition and protection.** The role of glycoproteins in immune recognition was mentioned earlier. Antibodies and other proteins attack and neutralize organisms that invade the body. Clotting proteins protect the body against blood loss.
- **Movement.** Movement is fundamental to all life, from the intracellular transport of molecules to the galloping of a racehorse. Proteins, with their special ability to change shape repeatedly, are the basis for all such movement. Some proteins are called *molecular motors* (*motor proteins*) for this reason. One prominent example is the myosin that drives all muscle contraction.
- **Cell adhesion.** Proteins bind cells to each other, which enables sperm to fertilize eggs, enables immune cells to bind to enemy cancer cells, and keeps tissues from falling apart.

2.4f Enzymes and Metabolism

Enzymes are macromolecules that function as biological catalysts. Some of them are ribonucleic acid (RNA) molecules called **ribozymes**, found in the ribosomes (see chapter 4). Most enzymes, however, are proteins. They enable biochemical reactions to occur rapidly at normal body temperatures. Enzymes were initially given somewhat arbitrary names, some of which are still with us, such as *pepsin* and *trypsin*. The modern system of naming enzymes, however, is more uniform and informative. It identifies the substance the enzyme acts upon, called its **substrate**; sometimes refers to the enzyme's action; and adds the suffix *-ase*. Thus, *amylase* digests starch (*amyl-* = starch) and *carbonic anhydrase* removes water (*anhydr-*) from carbonic acid. Enzyme names may be further modified to distinguish different forms of the same enzyme found in different tissues (see Deeper Insight 2.5).

To appreciate the effect of an enzyme, think of what happens when paper burns. Paper is composed mainly of glucose (in the form of cellulose). The burning of glucose can be represented by the equation

Paper doesn't spontaneously burst into flame because few of its molecules have enough kinetic energy to react. Lighting the paper with a match, however, raises the kinetic energy enough to initiate combustion (rapid oxidation). The energy needed to get the reaction started, supplied by the match, is called the **activation energy** (fig. 2.26a).

²⁵quater = fourth

²⁶prosthē = appendage, addition

²⁷lig = to bind

FIGURE 2.26 Effect of an Enzyme on Activation Energy. (a) Without catalysts, some chemical reactions proceed slowly because of the high activation energy needed to get molecules to react. (b) A catalyst facilitates molecular interaction, thus lowering the activation energy and making the reaction proceed more rapidly. Notice that the catalyzed reaction reaches completion in a shorter time.

? Does an enzyme release more energy from its substrate than an uncatalyzed reaction would release?

DEEPER INSIGHT 2.5

CLINICAL APPLICATION

Enzymes as Disease Markers

A given enzyme may exist in slightly different forms, called *isoenzymes*, in different cells. Isoenzymes catalyze the same chemical reactions but have enough structural differences that they can be distinguished by standard laboratory techniques. This is useful in the diagnosis of disease. When organs are diseased, some cells break down and release specific isoenzymes that can be detected in the blood. Normally, these isoenzymes would not be present in the blood or would have very low concentrations. An elevation in blood levels can help pinpoint what cells in the body have been damaged.

For example, creatine kinase (CK) occurs in different forms in different cells. An elevated serum level of CK-1 indicates a breakdown of skeletal muscle and is one of the signs of muscular dystrophy. An elevated CK-2 level indicates heart disease, because this isoenzyme comes only from cardiac muscle. There are five isoenzymes of lactate dehydrogenase (LDH). High serum levels of LDH-1 may indicate a tumor of the ovaries or testes, whereas LDH-5 may indicate liver disease or muscular dystrophy. Different isoenzymes of phosphatase in the blood may indicate bone or prostate disease.

In the body, we carry out the same reaction and oxidize glucose to water and carbon dioxide to extract its energy. We can't tolerate the heat of combustion in our bodies, however, so we must oxidize glucose in a more controlled way at a biologically feasible and safe temperature. Enzymes make this happen by lowering the activation energy—that is, by reducing the barrier to glucose oxidation (**fig. 2.26b**)—and by releasing the energy in small steps rather than a single burst of heat.

Enzyme Structure and Action

Figure 2.27 illustrates the action of an enzyme, using the example of *sucrase*, an enzyme that breaks sucrose down to glucose and fructose. The process occurs in three principal steps:

- 1 A substrate molecule (such as sucrose) approaches a pocket on the enzyme surface called the **active site**. Amino acid side groups in this region of the enzyme are arranged so as to bind functional groups on the substrate molecule. Many enzymes have two active sites, enabling them to bind two different substrates and bring them together in a way that makes them react more readily with each other.
- 2 The substrate binds to the enzyme, forming an **enzyme–substrate complex**. The fit between a particular enzyme and its substrate is often compared to a lock and key. Just as only one key fits a particular lock, sucrose is the only substrate that fits the active site of sucrase. Sucrase cannot digest other disaccharides such as maltose or lactose. This selectivity is called **enzyme–substrate specificity**. Unlike a simple lock and key, however, the substrate slightly changes the shape of the enzyme to create a better fit between the two, as shown by the arrows in the figure.
- 3 Sucrase breaks the bond between the two sugars of sucrose, adding —H^+ and —OH^- groups from water. This hydrolyzes sucrose to two monosaccharides, glucose and fructose, which are then released by the enzyme as its **reaction products**. The enzyme remains unchanged and is ready to repeat the process if another sucrose is available.

FIGURE 2.27 The Three Steps of an Enzymatic Reaction.

Since an enzyme is not consumed by the reaction it catalyzes, one enzyme molecule can consume millions of substrate molecules, and at astonishing speed. A single molecule of carbonic anhydrase, for example, breaks carbonic acid (H_2CO_3) down to H_2O and CO_2 at a rate of 36 million molecules per minute.

Factors that change the shape of an enzyme—notably temperature and pH—tend to alter or destroy the ability of the enzyme to bind its substrate. They disrupt the hydrogen bonds and other weak forces that hold the enzyme in its proper conformation, essentially changing the shape of the “lock” so that the “key” no longer fits. Enzymes vary in optimum pH according to where in the body they normally function. Thus, salivary amylase, which digests starch in the mouth, functions best at pH 7 and is inactivated when it is exposed to stomach acid; pepsin, which works in the acidic environment of the stomach, functions best around pH 2; and trypsin, a digestive enzyme that works in the alkaline environment of the small intestine, has an optimum pH of 9.5. Our internal body temperature is nearly the same everywhere, however, and all human enzymes have a temperature optimum near 37°C at which they produce their fastest reaction rates.

▶▶▶ APPLY WHAT YOU KNOW

Why does enzyme function depend on homeostasis?

Cofactors

About two-thirds of human enzymes require a nonprotein partner called a **cofactor**. Inorganic cofactors include iron, copper, zinc, magnesium, and calcium ions. Some of these work by binding to the enzyme and inducing it to fold into a shape that activates its active site. **Coenzymes** are organic cofactors usually derived from niacin, riboflavin, and other water-soluble vitamins. They accept electrons from an enzyme in one metabolic pathway and transfer them to an enzyme in another. For example, cells partially oxidize glucose through a pathway called *glycolysis*. A coenzyme called NAD^+ ,²⁸ derived from niacin, shuttles electrons from this pathway to another one called *aerobic respiration*, which uses energy from the electrons to make ATP (fig. 2.28). If NAD^+ is unavailable, the glycolysis pathway shuts down.

Metabolic Pathways

A **metabolic pathway** is a chain of reactions with each step usually catalyzed by a different enzyme. A simple metabolic pathway can be symbolized

where A is the initial *reactant*, B and C are *intermediates*, and D is the *end product*. The Greek letters above the reaction arrows represent enzymes that catalyze each step of the reaction. A is the substrate for enzyme α , B is the substrate for enzyme β , and C for enzyme γ . Such a pathway can be turned on or off by altering the conformation of any of these enzymes, thereby activating or deactivating them. This can be done by such means as the binding or dissociation of a cofactor, or by an end product of the pathway binding to an enzyme at an earlier step (product D binding to enzyme α and shutting off the reaction chain at that step, for example). In these and other ways, cells are able to turn on metabolic pathways when their end products are needed and shut them down when the end products are not needed.

FIGURE 2.28 The Action of a Coenzyme. A coenzyme such as NAD^+ acts as a shuttle that picks up electrons from one metabolic pathway (in this case, glycolysis) and delivers them to another (in this case, aerobic respiration).

²⁸nicotinamide adenine dinucleotide

FIGURE 2.29 Two Major Nucleotides. (a) Adenosine triphosphate (ATP). (b) Cyclic adenosine monophosphate (cAMP). The last two P~O bonds in ATP, indicated by wavy lines, are high-energy bonds.

2.4g ATP, Other Nucleotides, and Nucleic Acids

Nucleotides are organic compounds with three principal components: a single or double carbon–nitrogen ring called a *nitrogenous base*, a monosaccharide, and one or more phosphate groups. One of the best-known nucleotides is ATP (**fig. 2.29a**), in which the nitrogenous base is a double ring called *adenine*, the sugar is *ribose*, and there are three phosphate groups.

Adenosine Triphosphate

Adenosine triphosphate (ATP) is the body's most important energy-transfer molecule. It briefly gains energy from exergonic reactions such as glucose oxidation and releases it within seconds for physiological work such as polymerization reactions, muscle contraction, and pumping ions through cell membranes. The second and third phosphate groups of ATP are attached to the rest of the molecule by high-energy covalent bonds traditionally indicated by a wavy line (~) in the structural formula. Since phosphate groups are negatively charged, they repel each other. It requires a high-energy bond to overcome that repellent force and hold them together—especially to add the third phosphate group to a chain that already has two negatively charged phosphates. Most energy transfers to and from ATP involve adding or removing that third phosphate.

Enzymes called **adenosine triphosphatases (ATPases)** are specialized to hydrolyze the third phosphate bond, producing **adenosine diphosphate (ADP)** and an inorganic phosphate group (P_i). This reaction releases 7.3 kilocalories (kcal) of energy for

every mole (505 g) of ATP. Most of this energy escapes as heat, but we live on the portion of it that does useful work. We can summarize this as follows:

The free phosphate groups released by ATP hydrolysis are often added to enzymes or other molecules to activate them. This addition of P_i , called **phosphorylation**, is carried out by enzymes called **kinases**. The phosphorylation of an enzyme is sometimes the “switch” that turns a metabolic pathway on or off.

ATP is a short-lived molecule, usually consumed within 60 seconds of its formation. The entire amount in the body would support life for less than 1 minute if it weren't continually replenished. At a moderate rate of physical activity, a full day's supply of ATP would weigh twice as much as you do. Even if you never got out of bed, you would need about 45 kg (99 lb) of ATP to stay alive for a day. The reason cyanide is so lethal is that it halts ATP synthesis.

ATP synthesis is explained in detail in chapter 26, but you will find it necessary to become familiar with the general idea of it before you reach that chapter—especially in understanding muscle physiology (chapter 11). Much of the energy for ATP synthesis comes from glucose oxidation (**fig. 2.30**). The first stage in glucose oxidation (**fig. 2.31**) is the reaction pathway known as **glycolysis** (gly-COLL-ih-sis). This literally means “sugar splitting,” and indeed its major effect is to split the six-carbon glucose molecule into two three-carbon molecules of *pyruvate*. A little ATP is produced in this stage (a net yield of 2 ATP per glucose), but most of the chemical energy of the glucose is still in the pyruvate.

FIGURE 2.30 The Source and Uses of ATP.

What happens to pyruvate depends on how much oxygen is available relative to ATP demand. When the demand for ATP outpaces the oxygen supply, excess pyruvate is converted to lactate by a pathway called **anaerobic²⁹ fermentation** (AN-err-OH-bic). This pathway has two noteworthy disadvantages: First, it doesn't extract any more energy from pyruvate; second, the lactate it produces is toxic, so most cells can use anaerobic fermentation only as a temporary measure. The only advantage to this pathway is that it enables glycolysis to continue (for reasons explained in chapter 26) and thus enables a cell to continue producing a small amount of ATP.

If enough oxygen is available, a more efficient pathway called **aerobic respiration** occurs. This breaks pyruvate down to carbon dioxide and water and generates up to 30 more molecules of ATP for each of the original glucose molecules. The reactions of aerobic respiration are carried out in the cell's *mitochondria*, described in the next chapter, so mitochondria are regarded as a cell's principal "ATP factories."

Other Nucleotides

Guanosine triphosphate (GTP) (GWAH-no-seen) is another nucleotide involved in energy transfers. In some reactions, it donates phosphate groups to other molecules. For example, it can donate its third phosphate group to ADP to regenerate ATP.

Cyclic adenosine monophosphate (cAMP) (fig. 2.29b) is a nucleotide formed by the removal of both the second and third

FIGURE 2.31 ATP Production. Glycolysis produces pyruvate and a net gain of two ATPs. Anaerobic fermentation converts pyruvate to lactate and permits glycolysis to continue producing ATP in the absence of oxygen. Aerobic respiration produces a much greater ATP yield but requires oxygen.

phosphate groups from ATP. In many cases, when a hormone or other chemical signal ("first messenger") binds to a cell surface, it triggers an internal reaction that converts ATP to cAMP. The cAMP then acts as a "second messenger" to activate metabolic effects within the cell.

Nucleic Acids

Nucleic acids (new-CLAY-ic) are polymers of nucleotides. The largest of them, **deoxyribonucleic acid (DNA)**, is typically 100 million to 1 billion nucleotides long. It constitutes our genes, gives instructions for synthesizing all of the body's proteins, and transfers hereditary information from cell to cell when cells divide and from generation to generation when organisms reproduce. Three forms of **ribonucleic acid (RNA)**, which range from 70 to 10,000 nucleotides long, carry out those instructions and synthesize the proteins, assembling amino acids in the right order to produce each protein "described" by the DNA. The detailed structure of DNA and RNA and the mechanisms of protein synthesis and heredity are described in chapter 4.

²⁹an = without; aer = air, oxygen; obic = pertaining to life

DEEPER INSIGHT 2.6

CLINICAL APPLICATION

Steroid Abuse

It is routine news to hear of sports celebrities suspended or stripped of their honors for the use of anabolic steroids. Magazines of physical culture carry many tragic reports of the deaths of amateur athletes, or violent crimes committed by them, attributed to steroid abuse.

Anabolic steroids, as they are known on the street, are more properly called anabolic–androgenic³⁰ steroids. They are hormones derived from testosterone that stimulate muscle growth (the anabolic effect) and masculinize the body (the androgenic effect). Perhaps the earliest notion to put them to use arose in Nazi Germany, where testosterone was given to SS troops in an effort to make them more aggressive—but with no proven success. In the 1950s, however, when Soviet weight-lifting teams were routinely defeating American teams, it came to light that the Soviets were using testosterone as a performance enhancer. American team physician John Ziegler began experimenting with this back in the United States. He disliked the androgenic side effects and approached the Ciba Pharmaceutical Company to develop a testosterone analog (a molecule of slightly altered structure) that would enhance the anabolic effect and weaken the androgenic effect. Ciba soon developed Dianabol. It produced spectacular effects in weight lifters and by the 1960s, several testosterone analogs were freely and legally available, designed to enhance anabolic potency, reduce androgenic effects, and prolong the half-life of the drug in the body. Some are taken orally and others by intramuscular (I.M.) injection.

In limited doses, these steroids have legitimate medical uses such as the treatment of anemia, breast cancer, osteoporosis, and some muscle diseases and to prevent the atrophy of muscles in immobilized patients. Some amateur and professional athletes, however, use them in doses 10 to 1,000 times stronger than therapeutic doses. While such doses bulk up the muscles (**fig. 2.32**), they have hidden, devastating effects on the body. They raise cholesterol levels, which promotes fatty degeneration of the arteries (*atherosclerosis*). This can lead to coronary artery disease, heart and kidney failure, and stroke. Deteriorating circulation also sometimes results in gangrene, and many users have suffered amputation of the lower limbs as a result. As the liver attempts to dispose of the high concentration of steroids, liver cancer and other liver diseases may ensue. In addition, steroids suppress the immune system, so the user is more subject to infection and cancer. They cause a premature end to bone elongation, so people who use anabolic steroids in adolescence may never attain normal adult height.

Paradoxically, anabolic–androgenic steroids can have masculinizing effects on women and feminizing effects on men. In women, who are especially sensitive to the androgenic effect, the steroids commonly produce growth of facial hair, enlargement of the clitoris, atrophy of the breasts and uterus, and irregularities of ovulation and menstruation. The body converts excess testosterone to estrogens. In men, these can have a feminizing effect such as breast enlargement (*gynecomastia*), as well as cause atrophy of the testes, impotence (inability to achieve or maintain an erection), low sperm count, and infertility.

FIGURE 2.32 The Effect of Heavy Use of Anabolic–Androgenic Steroids.

Master1305/Shutterstock

Especially in men, steroid abuse can be linked to severe emotional disorders. Individuals vary in susceptibility, but the androgenic effects include heightened aggressiveness and unpredictable mood swings, so some abusers vacillate between depression and violence (“roid rage”), including physical abuse of family members and crimes as serious as homicide.

As the recreational use of anabolic–androgenic steroids became widespread, so did the tragic side effects of such heavy use—an outcome that Dr. Ziegler deeply regretted as the low point of his career. The U.S. Congress classified anabolic–androgenic steroids as a controlled substance in 1991. Their use in sports has been condemned by the American Medical Association and American College of Sports Medicine and banned by the International Olympic Committee, National Football League, Major League Baseball Players’ Association, National Basketball Association, and National Collegiate Athletic Association.

Yet in spite of such warnings and bans, many continue to use steroids and related performance-enhancing drugs, which remain available through unscrupulous coaches, physicians, Internet sources, and foreign mail-order suppliers under a cloud of confusing trade names (Durabolin, Anadrol, Oxandrin, Dianabol, Winstrol, Primobolan, and others). By some estimates, as many as 80% of competitive weight lifters, 30% of college and professional athletes, and 20% of male high-school athletes now use anabolic–androgenic steroids. The National Institutes of Health finds increasing use among high-school students and increasing denial that the steroids present a significant health hazard.

³⁰*andro* = male; *genic* = producing

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

16. Which reaction—dehydration synthesis or hydrolysis—converts a polymer to its monomers? Which one converts monomers to a polymer? Explain your answer.
17. What is the chemical name of blood sugar? What carbohydrate is polymerized to form starch and glycogen?
18. What is the main chemical similarity between carbohydrates and lipids? What are the main differences between them?
19. Explain the statement, All proteins are polypeptides but not all polypeptides are proteins.
20. Which is more likely to be changed by heating a protein, its primary structure or its tertiary structure? Explain.
21. Use the lock-and-key analogy to explain why excessively acidic body fluids (acidosis) could destroy enzyme function.
22. How does ATP change structure in the process of releasing energy?
23. What advantage and disadvantage does anaerobic fermentation have compared with aerobic respiration?
24. How is DNA related to nucleotides?

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

2.1 Atoms, Ions, and Molecules

1. The definition of *chemical element*; the six most abundant elements in the human body; and trace elements important in human physiology
2. The structure of an atom and the special functional relevance of its valence electrons
3. How isotopes of the same element differ from each other, and how radioisotopes differ from other isotopes
4. The clinical relevance of ionizing radiation; its three forms; the difference between the physical and biological half-life of a radioisotope; and the clinical relevance of that difference
5. The difference between an ion and an atom; how ions form; and the two types of ions and examples of each
6. How an electrolyte differs from an atom and from an ion; the most common ions that constitute electrolytes; and the functions and medical relevance of electrolytes
7. The definition of *free radical*; the medical relevance of free radicals; and how the body is partially protected against them
8. The definitions of *molecule* and *compound*
9. How isomers resemble and differ from each other
10. How a molecule's molecular weight is determined

11. The nature and distinguishing characteristics of ionic bonds, covalent bonds, hydrogen bonds, and van der Waals forces; how polar and nonpolar covalent bonds differ from each other; and how polar covalent bonds can give rise to hydrogen bonds

2.2 Water and Mixtures

1. How the biologically important properties of water arise from the polarity and bond angle of its molecules
2. The difference between a mixture and a compound
3. The differences between solutions, colloids, and suspensions, and examples of body fluids in each category
4. How pH is mathematically defined; the pH scale; and the meanings of *acid* and *base*
5. The action and physiological function of buffers
6. How various measures of chemical concentration differ from each other—weight per volume, percentage, molarity, and milliequivalents per liter—and how each unit of measure provides different kinds of information about the concentration of a solution

2.3 Energy and Chemical Reactions

1. The definition of *energy*, and the two basic forms of energy
2. The differences between decomposition, synthesis, and exchange reactions

3. What determines the direction of a reversible chemical reaction; the nature of a chemical equilibrium
4. Factors that determine the rate of a chemical reaction
5. The definition of *metabolism* and its two subdivisions
6. The difference between oxidation and reduction

2.4 Organic Compounds

1. The criterion for considering a compound to be organic
2. The difference between the carbon backbone and the functional group(s) of an organic molecule; the physiological relevance of functional groups
3. The structures of hydroxyl, methyl, carboxyl, amino, and phosphate functional groups
4. The difference between monomers and polymers; how dehydration synthesis and hydrolysis reactions convert one to the other; and the role of water in both types of reactions
5. The defining characteristics of carbohydrates and their principal roles in the body
6. The names of and basic structural differences between the three monosaccharides, three disaccharides, and three polysaccharides that are most abundant in the diet and most relevant in human physiology
7. The defining characteristics of lipids and their principal roles in the body
8. The major categories of lipids in human physiology, and the roles of each

STUDY GUIDE

9. How fatty acids and triglycerides are related through dehydration synthesis and hydrolysis reactions
10. The defining characteristics of amino acids and how the 20 amino acids involved in protein structure differ from each other
11. How amino acids are polymerized, and the structure of peptide bonds
12. Differences between a dipeptide, oligopeptide, polypeptide, and protein
13. The nature of the primary through quaternary levels of protein structure, and how an alpha helix differs from a beta sheet
14. Why protein function depends so strongly on the shape (conformation) of the molecule; how and why functionality is affected by denaturation; and the most common causes of protein denaturation
15. What defines a *conjugated* protein; the general term for the nonprotein component of such a molecule; and examples of conjugated proteins
16. The functions of proteins in human anatomy and physiology
17. How enzymes differ from other proteins, and the general role played by all enzymes
18. The general term for substances acted upon by enzymes; the relevance of active sites to enzyme action; why the active sites limit the range of substances on which an enzyme can act; and the name for this principle of selective enzyme action
19. The nature of cofactors and coenzymes, with examples
20. The term for a chain of linked enzymatic reactions; for its input and output; and for the intermediate steps between the input and output molecules
21. The basic structural components of adenosine triphosphate (ATP) and their organization in the molecule; the function of ATP and why life instantly ceases without it; and where in its molecular structure ATP carries the energy that is transferred to other chemicals
22. Differences between the aerobic and anaerobic mechanisms of producing ATP
23. How guanosine triphosphate (GTP) and cyclic adenosine monophosphate (cAMP) are related to ATP, and their functions
24. The basic chemical nature of the nucleic acids, DNA and RNA; their fundamental function; and how they are structurally related to ATP

▶ Testing Your Recall

Answers in Appendix A

1. A substance that _____ is considered to be a chemical compound.
 - a. contains at least two different elements
 - b. contains at least two atoms
 - c. has a chemical bond
 - d. has a stable valence shell
 - e. has covalent bonds
2. An ionic bond is formed when
 - a. two anions meet.
 - b. two cations meet.
 - c. an anion meets a cation.
 - d. electrons are unequally shared between nuclei.
 - e. electrons transfer completely from one atom to another.
3. The ionization of a sodium atom to produce Na^+ is an example of
 - a. oxidation.
 - b. reduction.
 - c. catabolism.
 - d. anabolism.
 - e. decomposition.
4. The weakest and most temporary of the following chemical bonds are
 - a. polar covalent bonds.
 - b. nonpolar covalent bonds.
 - c. hydrogen bonds.
 - d. ionic bonds.
 - e. double covalent bonds.
5. A substance capable of dissolving freely in water is
 - a. hydrophilic.
 - b. hydrophobic.
 - c. hydrolyzed.
 - d. hydrated.
 - e. amphipathic.
6. A carboxyl group is symbolized
 - a. $-\text{OH}$.
 - b. $-\text{NH}_2$.
 - c. $-\text{CH}_3$.
 - d. $-\text{CH}_2\text{OH}$.
 - e. $-\text{COOH}$.
7. The only polysaccharide synthesized in the human body is
 - a. cellulose.
 - b. glycogen.
 - c. cholesterol.
 - d. starch.
 - e. prostaglandin.
8. The arrangement of a polypeptide into a fibrous or globular shape is called its
 - a. primary structure.
 - b. secondary structure.
 - c. tertiary structure.
 - d. quaternary structure.
 - e. conjugated structure.
9. Which of the following functions is more characteristic of carbohydrates than of proteins?
 - a. contraction
 - b. energy storage
 - c. catalyzing reactions
 - d. immune defense
 - e. intercellular communication
10. The feature that most distinguishes a lipid from a carbohydrate is that a lipid has
 - a. more phosphate.
 - b. more sulfur.
 - c. a lower ratio of carbon to oxygen.
 - d. a lower ratio of oxygen to hydrogen.
 - e. a greater molecular weight.
11. When an atom gives up an electron and acquires a positive charge, it is called a/an _____.
 - a. cation
 - b. anion
 - c. molecule
 - d. ion
 - e. radical
12. Dietary antioxidants are important because they neutralize _____.
 - a. free radicals
 - b. enzymes
 - c. hormones
 - d. neurotransmitters
 - e. vitamins
13. Any substance that increases the rate of a reaction without being consumed by it is a/an _____. In the human body, _____ serve this function.
 - a. catalysts
 - b. cofactors
 - c. coenzymes
 - d. prosthetic groups
 - e. apoenzymes
14. All the synthesis reactions in the body form a division of metabolism called _____.
 - a. catabolism
 - b. anabolism
 - c. metabolism
 - d. homeostasis
 - e. equilibrium

STUDY GUIDE

15. A chemical reaction that joins two organic molecules into a larger one and produces water as a by-product is called _____.
16. The suffix _____ denotes a sugar, whereas the suffix _____ denotes an enzyme.
17. The amphipathic lipids of cell membranes are called _____.
18. A chemical named _____ is derived from ATP and widely employed as a “second messenger” in cellular signaling.
19. When oxygen is too limited to meet a cell’s ATP demand, a cell can employ a metabolic pathway called _____ to produce ATP.
20. A substance acted upon and changed by an enzyme is called the enzyme’s _____.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|----------|------------|-------------|
| 1. a- | 3. amphi- | 7. -mer |
| 2. aero- | 4. caloro- | 8. mono- |
| | 5. collo- | 9. oligo- |
| | 6. hydro- | 10. -philic |

► What’s Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|---|--|---|
| 1. The monomers of a polysaccharide are called amino acids. | 4. The products of catabolism contain more chemical energy than the reactants did. | 8. The higher the temperature is, the faster an enzyme works. |
| 2. Most of the body’s reserve energy is stored in the form of ATP. | 5. A polysaccharide is a chain of simple sugars joined by peptide bonds. | 9. Two percent sucrose and 2% sodium bicarbonate have the same number of molecules per liter of solution. |
| 3. Two molecules with the same atoms arranged in a different order are called isotopes. | 6. A saturated fat is defined as a fat to which no more carbon can be added. | 10. A solution of pH 8 has 10 times the hydrogen ion concentration of a solution with pH 7. |
| | 7. Enzymes are often consumed by the reactions they catalyze. | |

► Testing Your Comprehension

- | | | |
|---|--|--|
| 1. Suppose a pregnant woman with severe morning sickness has been vomiting steadily for several days. How will her loss of stomach acid affect the pH of her body fluids? Explain. | 3. In one form of nuclear decay, a neutron breaks down into a proton and electron and emits a gamma ray. Is this an endergonic or exergonic reaction, or neither? Is it an anabolic or catabolic reaction, or neither? Explain both answers. | 5. Some metabolic conditions such as diabetes mellitus cause disturbances in the acid–base balance of the body, which gives the body fluids an abnormally low pH. Explain how this could affect enzyme–substrate reactions and metabolic pathways in the body. |
| 2. Suppose a person with a severe anxiety attack hyperventilates and exhales CO ₂ faster than his body produces it. Consider the carbonic acid reaction in section 2.3b, and explain what effect this hyperventilation will have on his blood pH. (<i>Hint:</i> Remember the law of mass action.) | 4. How would the body’s metabolic rate be affected if there were no such thing as enzymes? Explain. | |

CELLULAR FORM AND FUNCTION

Dividing cancer cells. These are from a fibrosarcoma, a malignant tumor that arises from connective tissue cells called fibroblasts.

DEEPER INSIGHTS

- 3.1 Clinical Application: Calcium Channel Blockers
- 3.2 Clinical Application: Cystic Fibrosis
- 3.3 Evolutionary Medicine: Mitochondria—Evolution and Clinical Significance

BRUSHING UP

- The transport of matter through cell membranes follows the principles of flow down gradients (see section 1.6e).
- To adequately understand the structure of the cell surface, it is essential that you understand glycolipids and glycoproteins, as well as phospholipids and their amphipathic nature (see sections 2.4c and 2.4d).
- The proteins of cell membranes have a great variety of functions. To understand those depends on an acquaintance with the functions of proteins in general and how protein function depends on tertiary structure (see “Protein Structure” and “Protein Functions” in section 2.4e).

All organisms, from the simplest to the most complex, are composed of cells—whether the single cell of a bacterium or the trillions of cells that constitute the human body. These cells are responsible for all structural and functional properties of a living organism. A knowledge of cells is therefore indispensable to any true understanding of the workings of the human body, the mechanisms of disease, and the rationale of therapy. Thus, this chapter and the next one introduce the basic cell biology of the human body, and subsequent chapters expand upon this information as we examine the specialized cellular structure and function of specific organs.

3.1 Concepts of Cellular Structure

Expected Learning Outcomes

When you have completed this section, you should be able to

- discuss the development and modern tenets of the cell theory;
- describe cell shapes from their descriptive terms;
- state the size range of human cells and discuss factors that limit their size;
- discuss the way that developments in microscopy have changed our view of cell structure; and
- outline the major components of a cell.

3.1a Development of the Cell Theory

Cytology,¹ the scientific study of cells, was born in 1663 when Robert Hooke observed the empty cell walls of cork and coined the word *cellulae* (“little cells”) to describe them (see section 1.2). Soon he studied thin slices of fresh wood and saw living cells

“filled with juices”—a fluid later named *cytoplasm*. By the mid-1800s, with increasingly sophisticated instruments and methods of observation, scientists arrived at certain generalizations about cells that we now call the **cell theory**. This is credited especially to German physician–physiologist Theodor Schwann (1810–82) and German botanist Matthias Schleiden (1804–81). Although stated in various ways, the most essential points of the cell theory are:

- All living organisms are made of one or more cells.
- Cells are the basic structural and functional units of all living organisms. Nothing simpler than a cell, such as an organelle, DNA, or an enzyme, is alive in itself.
- All activities of an organism (including the human body) stem from the activities of its constituent cells. Cytology is therefore the foundation for all biological understanding of life.
- All cells arise from preexisting cells, not from nonliving matter, and they pass hereditary information from generation to generation of cells.

3.1b Cell Shapes and Sizes

We will shortly examine the structure of a generic cell, but the generalizations we draw shouldn’t blind you to the diversity of cellular form and function in humans. There are about 200 kinds of cells in the human body, with a variety of shapes, sizes, and functions.

Descriptions of organ and tissue structure often refer to the shapes of cells by the following terms (**fig. 3.1**):

- **Squamous**² (SKWAY-mus)—a thin, flat, scaly shape, often with a bulge where the nucleus is, much like the shape of a fried egg “sunny side up.” Squamous cells line the esophagus and air sacs (alveoli) of the lungs, and form the surface layer (epidermis) of the skin.
- **Cuboidal**³ (cue-BOY-dul)—squarish-looking in frontal sections and about equal in height and width; liver cells are a good example.
- **Columnar**—distinctly taller than wide, such as the inner lining cells of the stomach and intestines.
- **Polygonal**⁴—having irregularly angular shapes with four, five, or more sides, like the wax cells of a honeycomb. The densely packed cells of many glands are polygonal.
- **Stellate**⁵—having multiple pointed processes projecting from the body of a cell, giving it a somewhat starlike shape. The cell bodies of many nerve cells are stellate.

²squam = scale; ous = characterized by

³cub = cube; oidal = like, resembling

⁴poly = many; gon = angles

⁵stell = star; ate = resembling, characterized by

¹cyto = cell; logy = study of

FIGURE 3.1 Common Cell Shapes. **APR**

- **Spheroidal to ovoid**—round to oval, as in egg cells and white blood cells.
- **Discoidal**—disc-shaped, as in red blood cells.
- **Fusiform**⁶ (FEW-zih-form)—spindle-shaped; elongated, with a thick middle and tapered ends, as in smooth muscle cells.
- **Fibrous**—long, slender, and threadlike, as in skeletal muscle cells and the axons (nerve fibers) of nerve cells.

Some of these shapes refer to the way a cell looks in typical tissue sections, not to the complete three-dimensional shape of the cell. A cell that looks squamous, cuboidal, or columnar in a tissue section, for example, usually looks polygonal if viewed from its upper surface.

The most useful unit of measure for designating cell sizes is the **micrometer (μm)**, formerly called the micron—one-millionth (10^{-6}) of a meter, one-thousandth (10^{-3}) of a millimeter. (See appendix B for units of measurement.) The smallest objects most people can see with the naked eye are about 100 μm, which is about one-quarter the size of the period at the end of a typical sentence of print. A few human cells fall within this range, such as the egg cell and some fat cells, but most human cells are about 10 to 15 μm wide. The longest human cells are nerve cells (sometimes over a meter long) and muscle cells (up to 30 cm long), but both are usually too slender to be seen with the naked eye.

There are several factors that limit the size of cells. If a cell swelled to excessive size, it could rupture like an overfilled water balloon. In addition, cell size is limited by the relationship between its volume and surface area. The surface area of a cell is proportional to the square of its diameter, while volume is proportional to the cube of its diameter. Thus, for a given increase in diameter, volume increases much more than surface area. Picture a cuboidal cell 10 μm on each side (**fig. 3.2**). It would have a surface area of 600 μm² (10 μm × 10 μm × 6 sides) and a volume of 1,000 μm³ (10 × 10 × 10 μm). Now, suppose it grew by another 10 μm on each side. Its new surface area would be 2,400 μm² (20 μm × 20 μm × 6) and its volume would be 8,000 μm³ (20 × 20 × 20 μm). The 20 μm cell has eight times as much cytoplasm needing nourishment and waste removal, but only four times as much membrane surface through which wastes and nutrients can be exchanged. A cell that is too big cannot support itself.

Further, if a cell were too large, molecules couldn't diffuse from place to place fast enough to support its metabolism. The time required for diffusion is proportional to the square of distance, so if a cell diameter doubled, the travel time for molecules within the cell would increase fourfold. For example, if it took 10 seconds for a molecule to diffuse from the surface to the center of a cell with a 10 μm radius, then we increased the cell radius to 1 mm, it would take 278 hours to reach the center—far too slow to support the cell's life activities.

Having organs composed of many small cells instead of fewer large ones has another advantage. The death of one or a few cells has less effect on the structure and function of the whole organ.

⁶fusi = spindle; form = shape

FIGURE 3.2 The Relationship Between Cell Surface Area and Volume. As a cell doubles in diameter, its volume increases eightfold, but its surface area increases only fourfold. A cell that is too large may have too little plasma membrane to serve the metabolic needs of the increased volume of cytoplasm.

3.1c Basic Components of a Cell

In the nineteenth century, little was known about cells except that they were enclosed in a membrane and contained a nucleus. The fluid between the nucleus and surface membrane, its **cytoplasm**,⁷ was thought to be little more than a gelatinous mixture of chemicals and vaguely defined particles. The **transmission electron microscope (TEM)**, invented in the mid-twentieth century, radically changed this view. Using a beam of electrons in place of light, the TEM enabled biologists to see a cell's **ultrastructure**, a fine degree of detail extending even to the molecular level. The most important thing about a good microscope isn't magnification but **resolution**—the ability to reveal detail, to distinguish small, close-together objects from each other. Any image can be photographed and enlarged as much as we wish, but if enlargement fails to reveal any more useful detail, it is *empty magnification*.

⁷cyto = cell; plasm = formed, molded

A big blurry image isn't nearly as informative as one that's small and sharp. The TEM reveals far more detail than the light microscope (LM) (**fig. 3.3**). A later invention, the **scanning electron microscope (SEM)**, produces dramatic three-dimensional images at high magnification and resolution (see fig. 3.10a), but can view only surface features.

A stunning application of SEM, often seen in this book, is the *vascular corrosion cast* technique for visualizing the blood vessels of an organ. The vessels are drained and flushed with saline, then carefully filled with a resin. After the resin solidifies,

(a)

(b)

FIGURE 3.3 Magnification Versus Resolution. Cross sections of a skeletal muscle cell viewed by (a) light microscopy (LM) and (b) transmission electron microscopy (TEM). The TEM, with its better resolution, shows significantly finer detail, down to the protein filaments that produce muscle contraction.

a: Ed Reschke/Getty Images; b: Mediscan/Alamy Stock Photo

the actual tissue is dissolved with a corrosive agent such as potassium hydroxide. This leaves only a resin cast of the vessels, which is then photographed with the SEM. The resulting images are not only strikingly beautiful, but also give great insights into the blood supply to an organ from macro- to microscopic levels (see figs. 19.10c, 23.10a, and the opening page of chapter 17).

Table 3.1 gives the sizes of some cells and subcellular objects relative to the resolution of the naked eye, light microscope, and TEM. You can see why the very existence of cells was unsuspected until the light microscope was invented, and why little was known about their internal components until the TEM became available.

Figure 3.4 shows some major constituents of a typical cell. The cell is surrounded by a **plasma (cell) membrane** made of proteins and lipids. The composition and functions of this membrane can differ significantly from one region of a cell to another, especially between the basal, lateral, and apical (upper) surfaces of cells like the one pictured.

The cytoplasm is crowded with fibers, tubules, passages, and compartments. It contains the *cytoskeleton*, a supportive framework of protein filaments and tubules; an abundance of *organelles*, diverse structures that perform various metabolic tasks for the cell; and *inclusions*, which are foreign matter or stored cell products. A cell may have 10 billion protein molecules, including potent enzymes with the potential to destroy the cell if they're not contained and isolated from other cellular components. You can imagine the enormous problem of keeping track of all this material, directing molecules to the correct destinations, and maintaining order against nature's incessant trend toward disorder. Cells maintain order partly by compartmentalizing their contents in the organelles.

The cytoskeleton, organelles, and inclusions are embedded in a clear fluid called the **cytosol**⁸ or **intracellular fluid (ICF)**. All body fluids not contained in the cells are collectively called the **extracellular fluid (ECF)**. The ECF located amid the cells is also called **tissue (interstitial) fluid**. Some other extracellular fluids include blood plasma, lymph, and cerebrospinal fluid.

In summary, we regard cells as having the following major components:

- Plasma membrane
- Cytoplasm
 - Cytoskeleton
 - Organelles (including nucleus)
 - Inclusions
 - Cytosol

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. What are the basic principles of the cell theory?
2. What does it mean to say a cell is squamous, stellate, columnar, or fusiform?

⁸*cyto* = cell; *sol* = dissolved matter

TABLE 3.1 Sizes of Biological Structures in Relation to the Resolution of the Eye, Light Microscope, and Transmission Electron Microscope	
Object	Size
Visible to the Naked Eye (Resolution 70–100 μm)	
Human egg, diameter	100 μm
Visible with the Light Microscope (Resolution 200 nm)	
Most human cells, diameter	10–15 μm
Cilia, length	7–10 μm
Mitochondria, width × length	0.2 × 4 μm
Bacteria (<i>Escherichia coli</i>), length	1–3 μm
Microvilli, length	1–2 μm
Lysosomes, diameter	0.5 μm = 500 nm
Visible with the Transmission Electron Microscope (Resolution 0.5 nm)	
Nuclear pores, diameter	30–100 nm
Centriole, diameter × length	20 × 50 nm
Poliovirus, diameter	30 nm
Ribosomes, diameter	15 nm
Globular proteins, diameter	5–10 nm
Plasma membrane, thickness	7.5 nm
DNA molecule, diameter	2.0 nm
Plasma membrane channels, diameter	0.8 nm

3. Why can't cells grow to unlimited size?
4. What is the difference between cytoplasm and cytosol?
5. Define *intracellular fluid (ICF)* and *extracellular fluid (ECF)*.

3.2 The Cell Surface

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the structure of the plasma membrane;
- b. explain the functions of the lipid, protein, and carbohydrate components of the plasma membrane;
- c. describe a second-messenger system and discuss its importance in human physiology;
- d. explain the composition and functions of the glycocalyx that coats cell surfaces; and
- e. describe the structure and functions of microvilli, cilia, flagella, and pseudopods.

Many physiologically important processes occur at the surface of a cell—immune responses, the binding of egg and sperm, cell-to-cell signaling by hormones, and the detection of tastes and smells, for example. A substantial part of this chapter is therefore

FIGURE 3.4 Structure of a Representative Cell.

concerned with the cell surface. Like explorers of a new continent, we will examine the interior only after we've investigated its coastline. In this section, we examine the structure of the plasma membrane, surface features such as cilia and microvilli, and methods of transport through the membrane.

3.2a The Plasma Membrane

The plasma membrane defines the boundaries of the cell, governs its interactions with other cells, and controls the passage of materials into and out of the cell. It appears to the electron microscope as a pair of dark parallel lines with a total thickness of about

7.5 nm (**fig. 3.5a**). The side that faces the cytoplasm is the *intracellular face* of the membrane, and the side that faces outward is the *extracellular face*. Similar membranes enclose most of a cell's organelles and control their uptake and release of chemicals.

Membrane Lipids

Figure 3.5b shows our current concept of the molecular structure of the plasma membrane—an oily film of lipids with proteins embedded in it. Typically about 98% of the membrane molecules are lipids, and about 75% of those are phospholipids. These amphipathic molecules arrange themselves into a sandwichlike bilayer, with their hydrophilic phosphate-containing heads facing the water on each

side and their hydrophobic tails directed toward the center, avoiding the water. The phospholipids drift laterally from place to place, spin on their axes, and flex their tails. These movements keep the membrane fluid.

▶▶▶ APPLY WHAT YOU KNOW

What would happen if the plasma membrane were made primarily of a hydrophilic substance such as carbohydrate? Which of the major themes at the end of chapter 1 does this point best exemplify?

Cholesterol molecules, found near the membrane surfaces amid the phospholipids, constitute about 20% of the membrane lipids. By interacting with the phospholipids and holding them still, cholesterol can stiffen the membrane (make it less fluid) in spots. Higher concentrations of cholesterol, however, can increase membrane fluidity by preventing phospholipids from packing closely together.

The remaining 5% of the membrane lipids are glycolipids—phospholipids with short carbohydrate chains on the extracellular face of the membrane. They contribute to the *glycocalyx*, a carbohydrate coating on the cell surface with multiple functions, described shortly.

FIGURE 3.5 The Plasma Membrane. (a) Plasma membranes of two adjacent cells (TEM). (b) Molecular structure of the plasma membrane.

a: Dr. Donald Fawcett/Science Source

Membrane Proteins

Although proteins are only about 2% of the molecules of the plasma membrane, they're larger than lipids and average about 50% of the membrane by weight. There are two broad classes of membrane proteins: transmembrane and peripheral. **Transmembrane proteins** pass completely through the phospholipid bilayer, protruding from it on both sides. They have hydrophilic regions in contact with the water on both sides, and hydrophobic regions that pass back and forth through the lipid (**fig. 3.6**). Most transmembrane proteins are glycoproteins, bound to oligosaccharides on the extracellular side. Many of these proteins drift about freely in the phospholipid film, like ice cubes floating in a bowl of water. Others are anchored to the *cytoskeleton*—an intracellular system of tubules and filaments discussed later. **Peripheral proteins** don't protrude into the phospholipid layer but adhere to either the inner or outer face of the membrane. Those on the inner face are typically anchored to a transmembrane protein as well as to the cytoskeleton.

The functions of membrane proteins include:

- **Receptors (fig. 3.7a).** Many of the chemical signals by which cells communicate (epinephrine, for example) cannot enter the target cell but bind to surface proteins called receptors. Receptors are usually specific for one particular messenger, much like an enzyme that is specific for one substrate. Plasma membranes also have receptor proteins that bind chemicals and transport them into the cell, as discussed later in this chapter.

When a messenger binds to a surface receptor, it may trigger changes within the cell that produce a second messenger in the cytoplasm. This process involves both transmembrane proteins (the receptors) and peripheral proteins. Second-messenger systems are discussed shortly in more detail.

- **Enzymes (fig. 3.7b).** Enzymes in the plasma membrane carry out the final stages of starch and protein digestion in the small intestine, help produce second messengers, and break down hormones and other signaling molecules whose job is done, thus stopping them from excessively stimulating a cell.
- **Channel proteins (fig. 3.7c).** Channels are passages that allow water and hydrophilic solutes to move through the membrane. A channel is a tunnel that passes through a complex of multiple proteins or between subunits of an individual protein. Some of them, called **leak channels**, are always open and allow materials to pass through continually. Others, called **gates (gated channels)**, open and close under different circumstances and allow solutes through at some times, but not others (**fig. 3.7d**). These gates respond to three types of stimuli: **ligand-gated channels** respond to chemical messengers, **voltage-gated channels** to changes in electrical potential (voltage) across the plasma membrane, and **mechanically gated channels** to physical stress on a cell, such as stretch and pressure. By controlling the movement of electrolytes through the plasma membrane, gated channels play an important role in the timing of nerve signals and muscle contraction (see Deeper Insight 3.1). Some receptors double in function as gated channels. When a nerve stimulates a muscle, for example, a chemical from the nerve fiber binds to a receptor on the muscle fiber and the receptor opens to allow sodium and potassium ions to flow through and excite the muscle. Defects in channel proteins are responsible for a family of diseases called *channelopathies*.

FIGURE 3.6 Transmembrane Proteins. A transmembrane protein has hydrophobic regions embedded in the phospholipid bilayer and hydrophilic regions projecting into the intracellular and extracellular fluids. The protein may cross the membrane once (left) or multiple times (right). The intracellular regions are often anchored to the cytoskeleton by peripheral proteins.

FIGURE 3.7 Some Functions of Membrane Proteins.

- **Carriers** (see fig. 3.17). Carriers are transmembrane proteins that bind to glucose, electrolytes, and other solutes and transfer them to the other side of the membrane. Some carriers, called **pumps**, consume ATP in the process.
- **Cell-identity markers** (fig. 3.7e). Glycoproteins contribute to the glycocalyx, which acts like an “identification tag” that enables the immune system to tell which cells belong to one’s body and which are foreign invaders.
- **Cell-adhesion molecules** (fig. 3.7f). Cells adhere to one another and to extracellular material through membrane proteins called cell-adhesion molecules (CAMs). With few exceptions (such as blood cells and metastasizing cancer cells), cells don’t survive and grow normally unless they’re mechanically linked to the extracellular material. Special events such as sperm–egg binding and the binding of an immune cell to a cancer cell also require CAMs.

DEEPER INSIGHT 3.1

CLINICAL APPLICATION

Calcium Channel Blockers

Calcium channel blockers are a class of drugs that show the therapeutic relevance of understanding gated membrane channels. The walls of the arteries contain smooth muscle that contracts or relaxes to change their diameter. These changes modify the blood flow and strongly influence blood pressure. Blood pressure rises when the arteries constrict and falls when they relax and dilate. Excessive, widespread vasoconstriction can cause hypertension (high blood pressure), and vasoconstriction in the coronary blood vessels of the heart can cause pain (angina) due to inadequate blood flow to the cardiac muscle. In order to contract, a smooth muscle cell must open calcium channels in its plasma membrane and allow calcium to enter from the extracellular fluid. Calcium channel blockers prevent these channels from opening and thereby relax the arteries, increase blood flow, relieve angina, and lower the blood pressure.

Second Messengers

Second messengers are of such importance that they require a closer look. You will find this information essential for your later understanding of hormone and neurotransmitter action. Let’s consider how the hormone epinephrine stimulates a cell. Epinephrine, the “first messenger,” can’t pass through the plasma membrane, so it binds to a surface receptor. The receptor is linked on the intracellular side to a peripheral **G protein** (fig. 3.8). G proteins are named for the ATP-like chemical, guanosine triphosphate (GTP), from which they get their energy. When activated by the receptor, a G protein relays the signal to another membrane protein, **adenylate cyclase** (ah-DEN-ih-late SY-clase). Adenylate cyclase removes two phosphate groups from ATP and converts it to **cyclic AMP** (cAMP), the second messenger (see fig. 2.29b). Cyclic AMP then activates cytoplasmic enzymes called **kinases** (KY-nace-es), which add phosphate groups to other cellular enzymes. This activates some enzymes and deactivates others, but either way, it triggers a great variety of physiological changes within the cell. Up to 60% of drugs work by altering the activity of G proteins.

FIGURE 3.8 A Second-Messenger System.

? Is adenylate cyclase a transmembrane protein or a peripheral protein? What about the G protein?

3.2b The Glycocalyx

External to the plasma membrane, all animal cells have a fuzzy coat called the **glycocalyx**⁹ (GLY-co-CAY-licks) (**fig. 3.9**), composed of the carbohydrate moieties of membrane glycolipids and glycoproteins. It is chemically unique in everyone but identical twins, and acts like an identification tag that enables the body to distinguish its own healthy cells from transplanted tissues, invading organisms, and diseased cells. Human blood types and transfusion compatibility are determined by glycolipids. Functions of the glycocalyx are summarized in **table 3.2**.

3.2c Extensions of the Cell Surface

Many cells have surface extensions called *microvilli*, *cilia*, *flagella*, and *pseudopods*. These aid in absorption, movement, and sensory processes.

TABLE 3.2 Functions of the Glycocalyx	
Protection	Cushions the plasma membrane and protects it from physical and chemical injury
Immunity to infection	Enables the immune system to recognize and selectively attack foreign organisms
Defense against cancer	Changes in the glycocalyx of cancerous cells enable the immune system to recognize and destroy them
Transplant compatibility	Forms the basis for compatibility of blood transfusions, tissue grafts, and organ transplants
Cell adhesion	Binds cells together so tissues don't fall apart
Fertilization	Enables sperm to recognize and bind to eggs
Embryonic development	Guides embryonic cells to their destinations in the body

⁹glyco = sugar; calyx = cup, vessel

FIGURE 3.9 Microvilli and the Glycocalyx (TEM). The microvilli are anchored by microfilaments of actin, which occupy the core of each microvillus and project into the cytoplasm. (a) Longitudinal section, perpendicular to the cell surface. (b) Cross section.

a: Don W. Fawcett/Science Source; b: Biophoto Associates/Science Source

Microvilli

Microvilli¹⁰ (MY-cro-VIL-eye; singular, *microvillus*) are extensions of the plasma membrane that serve primarily to increase a cell's surface area (figs. 3.9 and 3.10a, c). They are best developed in cells specialized for absorption, such as the epithelial cells of the intestines and kidneys. They give such cells 15 to 40 times as much absorptive surface area as they would have if their apical surfaces were flat.

Individual microvilli can't be distinguished very well with the light microscope because they're only 1 to 2 μm long. On some cells, they're very dense and appear as a fringe called the **brush border** at the apical cell surface. With the scanning electron microscope, they resemble a deep-pile carpet. With the transmission electron microscope, microvilli typically look like finger-shaped projections of the cell surface. They show little internal structure, but some have a bundle of stiff filaments of a protein called *actin*. Actin filaments attach to the inside of the plasma membrane at the tip of the microvillus, and at its base they extend a little way into the cell and anchor the microvillus to a protein mesh called the *terminal web*. When tugged by another protein in the cytoplasm, actin can shorten a microvillus to milk its absorbed contents downward into the cell.

In contrast to the long, shaggy microvilli of absorptive cells, those on many other cells are little more than tiny bumps on the surface. On cells of the taste buds and inner ear, they are well developed but serve sensory rather than absorptive functions.

Cilia and Flagella

Cilia (SIL-ee-uh; singular, *cilium*¹¹) (fig. 3.10) are hairlike processes about 7 to 10 μm long. Nearly every human cell has a single, nonmotile *primary cilium* a few micrometers long. Its function in some cases is still a mystery, but many of them are sensory, serving as the cell's "antenna" for monitoring nearby conditions. In the inner ear, they play a role in the sense of balance; in the retina of the eye, they're highly elaborate and form the light-absorbing part of the receptor cells; and in the kidney, they're thought to monitor the flow of fluid as it is processed into urine. In some cases, they open calcium gates in the plasma membrane, activating an informative signal in the cell. Sensory cells in the nose have multiple nonmotile cilia that bind odor molecules. Defects in the development, structure, or function of cilia—especially these nonmotile primary cilia—are sometimes responsible for birth defects and hereditary diseases called

¹⁰micro = small; villi = hairs

¹¹cilium = eyelash

FIGURE 3.10 Cilia. (a) Epithelium of the uterine (fallopian) tube (SEM). The short, mucus-secreting cells between the ciliated cells show bumpy microvilli on their surfaces. (b) Three-dimensional structure of a cilium. (c) Cross section of a few cilia and microvilli (TEM). (d) Cross-sectional structure of a cilium. Note the relative sizes of cilia and microvilli in parts (a) and (c).

a: Science Photo Library/Alamy Stock Photo; c: Don Fawcett/Science Source

ciliopathies. (See Testing Your Comprehension question 5 at the end of this chapter.)

Motile cilia are less widespread, but more numerous on the cells that do have them. They occur in the respiratory tract, uterine (fallopian) tubes, internal cavities (*ventricles*) of the brain, and short ducts (*efferent ductules*) associated with the testes. There may be 50 to 200 cilia on the surface of one cell. They beat in waves that sweep across the surface of an epithelium, always in the

same direction (**fig. 3.11**), propelling such materials as mucus, an egg cell, or cerebrospinal fluid. Each cilium bends stiffly forward and produces a *power stroke* that pushes along the mucus or other matter. Shortly after a cilium begins its power stroke, the one just ahead of it begins, and the next and the next—collectively producing a wavelike motion. After a cilium completes its power stroke, it pulls limply back in a *recovery stroke* that restores it to the upright position, ready to flex again.

FIGURE 3.11 Ciliary Action. (a) Cilia of an epithelium moving mucus along a surface layer of saline. (b) Power and recovery strokes of an individual cilium. The cilium goes limp on the recovery stroke to return to its original position without touching the mucus above.

▶▶▶ APPLY WHAT YOU KNOW

How would the movement of mucus in the respiratory tract be affected if cilia were equally stiff on both their power and recovery strokes?

Cilia couldn't beat freely if they were embedded in sticky mucus (see Deeper Insight 3.2). Instead, they beat within a saline layer at the cell surface. *Chloride pumps* in the apical plasma membrane produce this layer by pumping Cl^- into the extracellular fluid. Sodium ions follow by electrostatic attraction and water follows by osmosis. Mucus essentially floats on the surface of this layer and is pushed along by the tips of the cilia.

The structural basis for ciliary movement is a core called the **axoneme**¹² (ACK-so-neem), which consists of an array of thin protein cylinders called *microtubules*. There are two central microtubules surrounded by a ring of nine microtubule pairs—an arrangement called the *9 + 2 structure*. In cross section, it is reminiscent of a Ferris wheel (fig. 3.10d). The central microtubules

¹²*axo* = axis; *neme* = thread

DEEPER INSIGHT 3.2

CLINICAL APPLICATION

Cystic Fibrosis

The significance of chloride pumps is especially evident in *cystic fibrosis* (CF), a hereditary disease affecting primarily White children of European descent. CF is usually caused by a defect in which cells make chloride pumps but fail to install them in the plasma membrane. Consequently, there is an inadequate saline layer on the cell surface and the mucus is dehydrated and overly sticky. This thick mucus plugs the ducts of the pancreas and prevents it from secreting digestive enzymes into the small intestine, so digestion and nutrition are compromised. In the respiratory tract, the mucus clogs the cilia and prevents them from beating freely. The respiratory tract becomes congested with thick mucus, often leading to chronic infection and pulmonary collapse. The mean life expectancy of people with CF is about 44 years.

stop at the cell surface, but the peripheral microtubules continue a short distance into the cell as part of a **basal body** that anchors the cilium. In each pair of peripheral microtubules, one tubule has two little **dynein**¹³ arms (DINE-een). Dynein, a motor protein, uses energy from ATP to crawl up the adjacent pair of microtubules. On one side of the cilium, activated dynein arms reach out and attach to a microtubule of an adjacent pair, then flex and pull that microtubule toward them. Their collective action makes the cilium bend in that direction. Dynein arms on the other side of the cilium are inhibited at that time so they don't resist the bending. Then the first dyneins are inhibited and the others are activated, causing a reverse bend in that direction. Activation and inhibition repeatedly switch sides, causing the back and forth bending of the cilium's power and recovery strokes.

The microtubules of a cilium also act like monorail tracks along which motor proteins carry materials up and down the cilium for use in its growth and maintenance. The primary cilia, which cannot move, lack the two central microtubules and dynein arms, but still have the nine peripheral pairs; they are said to have a *9 + 0 structure*.

The only functional **flagellum**¹⁴ (fla-JEL-um) in humans is the whiplike tail of a sperm. It is much longer than a cilium and has an axoneme surrounded by a sheath of coarse fibers that stiffen the tail and give it more propulsive power. A flagellum beats by the same dynein-powered mechanism as cilia, but not in power and recovery strokes. Instead, it beats in a more undulating, snakelike or corkscrew fashion. It is described in further detail as part of sperm structure in chapter 27.

Pseudopods

Pseudopods¹⁵ (SOO-do-pods) are cytoplasm-filled extensions of the cell varying in shape from fine, filamentous processes to blunt fingerlike ones (fig. 3.12). Unlike the other three kinds of surface extensions, they change continually. Some form anew as the cell

¹³*dyn* = power, energy; *in* = protein

¹⁴*flagellum* = whip

¹⁵*pseudo* = false; *pod* = foot

FIGURE 3.12 Pseudopods. (a) *Amoeba*, a freshwater organism that crawls and captures food by means of pseudopods. (b) A neutrophil (white blood cell) that similarly uses pseudopods for locomotion and capturing bacteria. (c) A macrophage extending filamentous pseudopods to snare and “reel in” bacteria (the red rods).

surface bubbles outward and cytoplasm flows into a lengthening pseudopod, while others are retracted into the cell by disassembling protein filaments that supported them like a scaffold.

The freshwater organism *Amoeba* furnishes a familiar example of pseudopods, which it uses for locomotion and food capture. White blood cells called *neutrophils* crawl about like amoebae by means of fingerlike pseudopods, and when they encounter a bacterium or other foreign particle, they reach out with their pseudopods to surround and engulf it. *Macrophages*—tissue cells derived from certain white blood cells—reach out with thin filamentous pseudopods to snare bacteria and cell debris and “reel them in” to be digested by the cell. Like little janitors, macrophages thereby keep our tissues cleaned up. Blood platelets reach out with thin pseudopods to adhere to each other and to the walls of damaged blood vessels, forming plugs that temporarily halt bleeding.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- How does the structure of a plasma membrane depend on the amphipathic nature of phospholipids?
- Define *peripheral* versus *transmembrane* proteins.
- Explain the differences between a receptor, pump, and cell-adhesion molecule.
- How does a gate differ from other channel proteins? What three factors open and close membrane gates?
- What related roles do cAMP, adenylate cyclase, and kinases play in cellular function?
- Identify several reasons why the glycocalyx is important to human survival.
- How do microvilli and cilia differ in structure and function?

3.3 Membrane Transport

Expected Learning Outcomes

When you have completed this section, you should be able to

- explain what is meant by a *selectively permeable* membrane;
- describe the various mechanisms for transporting material through cellular membranes; and
- define *osmolarity* and *tonicity* and explain their importance.

One of the most important functions of cellular membranes is to control the passage of materials into and out of the organelles and the cell as a whole. The plasma membrane is both a barrier and gateway between the cytoplasm and ECF. It is **selectively permeable**—it allows some things through, such as nutrients and wastes, but usually prevents other things, such as proteins and phosphates, from entering or leaving the cell.

The methods of moving substances through the membrane can be classified in two overlapping ways: as passive or active mechanisms and as carrier-mediated or not. *Passive* mechanisms require no energy (ATP) expenditure by the cell. In most cases, the random molecular motion of the particles themselves provides the necessary energy. Passive mechanisms include filtration, diffusion, and osmosis. *Active* mechanisms, however, consume ATP. These include active transport and vesicular transport. *Carrier-mediated* mechanisms use a membrane protein to transport substances from one side of the membrane to the other, but some transport processes, such as osmosis, do not involve carriers.

3.3a Filtration

Filtration is a process in which a physical pressure forces fluid through a selectively permeable membrane. A coffee filter is an everyday example. The weight of the water drives water and dissolved matter through the filter, while the filter holds back larger particles (the coffee grounds). In physiology, the most important case of filtration is seen in the blood capillaries, where blood pressure forces fluid through gaps in the capillary wall (**fig. 3.13**). This is how water, salts, nutrients, and other solutes are transferred from the bloodstream to the tissue fluid and how the kidneys filter wastes from the blood. Capillaries hold back larger particles such as blood cells and proteins. In most cases, water and solutes filter through narrow gaps between the capillary cells. In some capillaries, however, the cells have large *filtration pores* through them, like the holes in a slice of Swiss cheese, allowing for more rapid filtration of large solutes such as protein hormones.

3.3b Simple Diffusion

Simple diffusion is the net movement of particles from a place of high concentration to a place of lower concentration as a result of their constant, spontaneous motion. In other words, substances diffuse *down their concentration gradients* (see “Gradients and Flow,” section 1.6e). Molecules move at astonishing speeds.

FIGURE 3.13 Filtration Through the Wall of a Blood

Capillary. Water and small solutes pass through gaps between cells, while blood cells and other large particles are held back.

At body temperature, the average water molecule moves about 2,500 km/h (1,500 mi./h)! However, molecules are so crowded they can travel only a short distance before colliding with each other and careening off in a new direction, like colliding billiard balls. The rate of diffusion, therefore, is much slower than the speed of molecular motion.

Diffusion occurs readily in air or water and doesn't necessarily need a membrane—for example, when an odor spreads from its source to your nose. However, if there is a membrane in the path of the diffusing molecules, and if it is permeable to that substance, the molecules will pass from one side of the membrane to the other. This is how oxygen passes from the air we inhale into the bloodstream. Dialysis treatment for kidney patients is based on diffusion of solutes through artificial *dialysis membranes*.

Diffusion rates are important to cell survival because they determine how quickly a cell can acquire nutrients or rid itself of wastes. Some factors that affect the rate of diffusion through a membrane are as follows:

- **Temperature.** Diffusion is driven by the kinetic energy of the particles, and temperature is a measure of that kinetic energy. The warmer a substance is, the more rapidly its particles diffuse. This is why sugar diffuses more quickly through hot tea than through iced tea.
- **Molecular weight.** Heavy molecules such as proteins move more sluggishly and diffuse more slowly than light particles such as electrolytes and gases. Small molecules also pass through membrane pores more easily than large ones.
- **“Steepness” of the concentration gradient.** The steepness of a gradient refers to the concentration difference between two points. Particles diffuse more rapidly if there is a greater concentration difference, like a ball rolling faster down a steeper slope.
- **Membrane surface area.** As noted earlier, the apical surface of cells specialized for absorption (for example, in the small intestine) is often extensively folded into microvilli.

This makes more membrane available for particles to diffuse through.

- **Membrane permeability.** Diffusion through a membrane depends on how permeable it is to the particles. For example, potassium ions diffuse more rapidly than sodium ions through a plasma membrane. Nonpolar, hydrophobic, lipid-soluble substances such as oxygen, nitric oxide, alcohol, and steroids diffuse through the phospholipid regions of a plasma membrane. Water and small charged, hydrophilic solutes such as electrolytes don't mix with lipids but diffuse primarily through channel proteins in the membrane. Cells can adjust their permeability to such a substance by adding channel proteins to the membrane, by taking them away, or by opening and closing membrane gates.

3.3c Osmosis

Osmosis¹⁶ is the net flow of water from one side of a selectively permeable membrane to the other. It is crucial to the body's water distribution (fluid balance). Imbalances in osmosis underlie such problems as diarrhea, constipation, hypertension, and edema (tissue swelling); osmosis also is a vital consideration in intravenous (I.V.) fluid therapy.

Osmosis occurs through nonliving membranes, such as cellophane and dialysis membranes, and through the plasma membranes of cells. The usual direction of net movement is from the more watery side, with a lower concentration of dissolved matter, to the less watery side, with a greater concentration of solute. The reason for the accumulation of water on the high-solute side is that when water molecules encounter a solute particle, they tend to associate with it to form a *hydration sphere* (see fig. 2.9). Even though this is a loose, reversible attraction, it does make those water molecules less available to diffuse back across the membrane to the side they came from. In essence, solute particles on one side of the membrane draw water away from the other side. Thus, water accumulates on the side with the most solute. All of this assumes that the solute molecules in question can't pass through the membrane, but stay on one side. The rate and direction of osmosis depend on the relative concentration of these nonpermeating solutes on the two sides of the membrane.

Significant amounts of water pass even through the hydrophobic, phospholipid regions of a plasma membrane, but water passes more easily through channel proteins called **aquaporins**,¹⁷ specialized for water. Cells can increase the rate of osmosis by installing more aquaporins in the membrane or decrease the rate by removing them. Certain cells of the kidney, for example, regulate the rate of urinary water loss by adding or removing aquaporins.

A cell can exchange a tremendous amount of water by osmosis. In red blood cells, for example, the amount of water passing through the plasma membrane every second is 100 times the volume of the cell.

¹⁶*osm* = push, thrust; *osis* = condition, process

¹⁷*aqua* = water; *por* = pore; *in* = protein

Figure 3.14 is a conceptual model of osmosis. Imagine a chamber divided by a selectively permeable membrane. Side A contains distilled water and side B contains large particles of a *nonpermeating* solute—that is, a solute such as protein that cannot pass through the membrane pores because of its size or other properties. Water molecules pass from side A to B (fig. 3.14a) and cling to the solute molecules on side B, hindering their movement back to side A.

Under such conditions, the water level in side A would fall and the level in side B would rise. It may seem as if this would continue indefinitely until side A dried up. This would not happen, however, because as water accumulated in side B, it would become heavier and exert more force, called **hydrostatic pressure**, on that side of the membrane. This would cause some filtration of water from B back to A. At some point, the rate of filtration would equal the rate of “forward” osmosis, water would pass through the membrane equally in both directions, and net osmosis would slow down and stop. At this point, an equilibrium (balance between opposing forces) would exist. The hydrostatic pressure required on side B to halt osmosis is called **osmotic pressure**. The more nonpermeating solute there is in B, the greater the osmotic pressure.

FIGURE 3.14 Osmosis. The dashed line represents a selectively permeable membrane dividing the chamber in half. (a) Initial net flow of water from side A to side B. (b) Equilibrium between osmotic and hydrostatic pressure, hence between osmosis and filtration, with no net flow. Water molecules aggregate around solute molecules and thus accumulate on side B.

▶▶▶ APPLY WHAT YOU KNOW

If the solute concentration on side B was half what it was in the original experiment, would the fluid on that side reach a higher or lower level than before? Explain.

Reverse osmosis is a process in which a mechanical pressure applied to one side of the system can override osmotic pressure and drive water through a membrane against its concentration gradient. This principle is used to create highly purified water for laboratory use and to desalinate seawater, converting it to drinkable freshwater—important for arid countries and ships at sea. The body’s principal pump, the heart, drives water out of the smallest blood vessels (the capillaries) by reverse osmosis—a process called *capillary filtration*. The equilibrium between osmosis and filtration will be an important consideration when we study fluid exchange by the capillaries in chapter 20. Blood plasma also contains albumin. In the preceding discussion, side B is analogous to the high-protein bloodstream and side A to the low-protein tissue fluid surrounding the capillaries. Water leaves the capillaries by filtration, but this is approximately balanced by water reentering the capillaries by osmosis.

3.3d Osmolarity and Tonicity

The **osmolarity**, or osmotic concentration, of body fluids has such a great effect on cellular function that it is important to understand the units in which it is measured. Physiologists and clinicians usually express this in terms of **milliosmoles per liter (mOsm/L)**, a unit of measure that expresses the quantity of nonpermeating particles per liter of solution. The basis of this unit of concentration is explained in appendix B. Blood plasma, tissue fluid, and intracellular fluids measure about 300 mOsm/L.

Tonicity is the ability of a solution to affect the fluid volume and pressure in a cell. If a solute cannot pass through a plasma membrane but remains more concentrated on one side than on the other, it causes osmosis. A **hypotonic**¹⁸ solution has a lower concentration of nonpermeating solutes than the intracellular fluid (ICF). Cells in a hypotonic solution absorb water, swell, and may burst (*lyse*) (fig. 3.15a). Distilled water is the extreme example; a sufficient quantity given to a person intravenously would lyse the blood cells, with dire consequences. A **hypertonic**¹⁹ solution is one with a higher concentration of nonpermeating solutes than the ICF. It causes cells to lose water and shrivel (*crenate*) (fig. 3.15c). Such cells may die of torn membranes and cytoplasmic loss. In **isotonic**²⁰ solutions, the total concentration of nonpermeating solutes is the same as in the ICF—hence, isotonic solutions cause no change in cell volume or shape (fig. 3.15b).

It is essential for cells to be in a state of osmotic equilibrium with the fluid around them, and this requires that the ECF have the same concentration of nonpermeating solutes as the ICF. Intravenous fluids given to patients are usually isotonic solutions, but

¹⁸*hypo* = less; *ton* = tension

¹⁹*hyper* = more; *ton* = tension

²⁰*iso* = equal; *ton* = tension

FIGURE 3.15 Effects of Tonicity on Red Blood Cells (RBCs). (a) RBC swelling in a hypotonic medium such as distilled water. (b) Normal RBC size and shape in an isotonic medium such as 0.9% NaCl. (c) RBC shriveling in a hypertonic medium such as 2% NaCl.

a–c: David M. Phillips/Science Source

hypertonic or hypotonic fluids are given for special purposes. A 0.9% solution of NaCl, called *normal saline*, is isotonic to human blood cells.

It is important to note that osmolarity and tonicity are not the same. Urea, for example, is a small organic molecule that easily penetrates plasma membranes. If cells are placed in 300 mOsm/L urea, urea diffuses into them (down its concentration gradient), water follows by osmosis, and the cells swell and burst. Thus, 300 mOsm/L urea is not isotonic to the cells. Sodium chloride, by contrast, penetrates plasma membranes poorly. In 300 mOsm/L NaCl, there is little change in cell volume; this solution is isotonic to cells.

3.3e Carrier-Mediated Transport

The processes of membrane transport described up to this point don't necessarily require a cell membrane; they can occur as well through artificial membranes. Now, however, we come to processes for which a cell membrane is necessary, because they employ transport proteins, or carriers. Thus, the next three processes are classified as **carrier-mediated transport**. In these cases, a solute binds to a carrier in the plasma membrane, which then changes shape and releases the solute to the other side. Carriers can move substances into or out of a cell, and into or out of organelles within the cell. The process is very rapid; for example, one carrier can transport 1,000 glucose molecules per second across the membrane.

Carriers act like enzymes in some ways: The solute is a ligand that binds to a specific receptor site on the carrier, like a substrate binding to the active site of an enzyme. The carrier exhibits **specificity** for its ligand, just as an enzyme does for its substrate. A glucose carrier, for example, can't transport fructose. Carriers also exhibit **saturation**; as the solute concentration rises, its rate of transport increases, but only up to a point. When every carrier molecule is occupied, adding

more solute can't make the process go any faster. The carriers are saturated—no more are available to handle the increased demand, and transport levels off at a rate called the **transport maximum (T_m)** (fig. 3.16). You could think of carriers as analogous to buses. If all the buses on a given line are full ("saturated"), they can't carry any more passengers, regardless of how many people are waiting at the bus stop. As we'll see in chapter 23, the T_m explains why glucose appears in the urine of people with diabetes mellitus.

An important difference between a carrier and an enzyme is that carriers don't chemically change their ligands; they simply

FIGURE 3.16 Carrier Saturation and Transport Maximum. Up to a point, increasing the solute concentration increases the rate of transport through a membrane. At the transport maximum (T_m), however, all carrier proteins are busy and cannot transport the solute any faster, even if more solute is added.

pick them up on one side of the membrane and release them, unchanged, on the other.

There are three kinds of carriers: uniports, symports, and antiports. A **uniport**²¹ carries only one type of solute. For example, most cells pump out calcium by means of a uniport, maintaining a low intracellular concentration so calcium salts don't crystallize in the cytoplasm. Some carriers move two or more solutes through a membrane simultaneously in the same direction; this process is called **cotransport**²² and the carrier protein that performs it is called a **symport**.²³ For example, absorptive cells of the small intestine and kidneys have a symport that takes up sodium and glucose simultaneously. Other carriers move two or more solutes in opposite directions; this process is called **countertransport** and the carrier protein is called an **antiport**.²⁴ For example, nearly all cells have an antiport called the *sodium-potassium pump* that continually removes Na^+ from the cell and brings in K^+ .

There are three mechanisms of carrier-mediated transport: facilitated diffusion, primary active transport, and secondary active transport. **Facilitated**²⁵ **diffusion** (fig. 3.17) is the carrier-mediated transport of a solute through a membrane *down its concentration gradient*. It requires no expenditure of metabolic energy (ATP) by the cell. It transports solutes such as glucose

that cannot pass through the membrane unaided. The solute attaches to a binding site on the carrier, then the carrier changes conformation and releases the solute on the other side of the membrane.

Primary active transport is a process in which a carrier moves a substance through a cell membrane *up its concentration gradient* using energy provided by ATP. Just as rolling a ball up a ramp would require you to push it (an energy input), this mechanism requires energy to move material up its concentration gradient. ATP supplies this energy by transferring a phosphate group to the transport protein. The calcium pump mentioned previously uses this mechanism. Even though Ca^{2+} is already more concentrated in the ECF than within the cell, this carrier pumps still more of it out. Active transport also enables cells to absorb amino acids that are already more concentrated in the cytoplasm than in the ECF.

Secondary active transport also requires an energy input, but depends only indirectly on ATP. For example, certain kidney tubules have proteins called *sodium-glucose transporters (SGLTs)* that simultaneously bind sodium (Na^+) and glucose and transport them into the tubule cells, saving glucose from being lost in the urine (fig. 3.18). An SGLT itself doesn't use ATP. However, it depends on the fact that the cell actively maintains a low internal Na^+ concentration, so Na^+ diffuses down its gradient into the cell. Glucose "hitches a ride" with the incoming Na^+ . But what keeps the intracellular Na^+ concentration low is that the basal membrane of the cell has an ATP-driven sodium-potassium pump that constantly removes Na^+ from the cell. If not for this, the Na^+ and glucose inflow via the SGLT would soon cease. Therefore, the SGLT doesn't use ATP directly, but depends on ATP to drive the

²¹uni = one; port = carry

²²co = together; trans = across; port = carry

²³sym = together; port = carry

²⁴anti = opposite; port = carry

²⁵facil = easy

FIGURE 3.17 Facilitated Diffusion. Note that the solute moves down its concentration gradient.

FIGURE 3.18 Secondary Active Transport. In this example, the sodium–glucose transporter (SGLT) at the apical cell surface carries out facilitated diffusion, but depends on active transport by the Na^+/K^+ pump at the base of the cell to keep it running.

Na^+/K^+ pump; it is therefore a secondary active-transport protein. (*Secondary active transport* is an unfortunate name for this, as the SGLT is actually carrying out facilitated diffusion, but its dependence on a primary active-transport pump has led to this name.)

The **sodium–potassium (Na^+/K^+) pump** itself (fig. 3.19) is a good example of primary active transport. It is also known as Na^+/K^+ ATPase because it is an enzyme that hydrolyzes ATP. The Na^+/K^+ pump binds three Na^+ simultaneously on the cytoplasmic side of the membrane, releases these to the ECF, binds two K^+ simultaneously from the ECF, and releases these into the cell. Each cycle of the pump consumes one ATP and exchanges three Na^+ for two K^+ . This keeps the K^+ concentration higher and the Na^+ concentration lower within the cell than they are in the ECF. These ions continually leak through the membrane, and the Na^+/K^+ pump compensates like bailing out a leaky boat.

Lest you question the importance of the Na^+/K^+ pump, consider that half of the calories you use each day go to this purpose alone. The pump typically operates at about 10 cycles/s, but under certain conditions it can achieve 100 cycles/s. Various types of cells have from just a few hundred Na^+/K^+ pumps (red blood cells) to millions of them (nerve cells), so an average cell may exchange 30 million Na^+ ions and 20 million K^+ ions and consume 10 million ATPs per second. Beyond compensating for a leaky plasma membrane, the Na^+/K^+ pump has at least four functions:

1. **Secondary active transport.** It maintains a steep Na^+ concentration gradient across the membrane. Like water behind a dam, this gradient is a source of potential energy that can be tapped to do other work. The SGLT described previously is an example of this.
2. **Regulation of cell volume.** Certain anions are confined to the cell and can't penetrate the plasma membrane. These “fixed anions,” such as proteins and phosphates, attract and retain cations. If there were nothing to correct for it, the retention of these ions would cause osmotic swelling and possibly lysis of the cell. Cellular swelling, however, elevates activity of the Na^+/K^+ pumps. Since each cycle of the pump removes one ion more than it brings in, the pumps are part of a negative feedback loop that reduces intracellular ion concentration, controls osmolarity, and prevents cellular swelling.

FIGURE 3.19 The Sodium–Potassium Pump (Na^+/K^+ ATPase).

? Why would the Na^+/K^+ pump, but not osmosis, cease to function after a cell dies?

3. **Maintenance of a membrane potential.** All living cells have an electrical charge difference called the *resting membrane potential* across the plasma membrane. Like the two poles of a battery, the inside of the membrane is negatively charged and the outside is positively charged. This difference stems from the unequal distribution of ions on the two sides of the membrane, maintained by the Na^+/K^+ pump. The membrane potential is essential to the excitability of nerve and muscle cells.
4. **Heat production.** When the weather turns chilly, we turn up not only the furnace in our home but also the “furnace” in our body. Thyroid hormone stimulates cells to produce more Na^+/K^+ pumps. As these pumps consume ATP, they release heat from it, compensating for the body heat we lose to the cold air around us.

▶▶▶ APPLY WHAT YOU KNOW

An important characteristic of proteins is their ability to change shape in response to the binding or dissociation of a ligand (see “Protein Structure” in section 2.4e). Explain how this is essential to carrier-mediated transport.

In summary, carrier-mediated transport is any process in which solute particles move through a membrane by means of a transport protein. The protein is a uniport if it transports only one solute, a symport if it carries two types of solutes at once in the same direction, and an antiport if it carries two or more solutes in opposite directions. If the carrier doesn’t depend on ATP at all and it moves solutes down their concentration gradient, the process is called facilitated diffusion. If the carrier itself consumes ATP and moves solutes up their concentration gradient, the process is called primary active transport. If the carrier doesn’t directly use ATP, but depends on a concentration gradient produced by ATP-consuming Na^+/K^+ pumps elsewhere in the plasma membrane, the process is called secondary active transport.

3.3f Vesicular Transport

So far, we have considered processes that move one or a few ions or molecules at a time through the plasma membrane. **Vesicular transport** processes, by contrast, move large particles, droplets of fluid, or numerous molecules at once through the membrane, contained in bubblelike **vesicles** of membrane. Vesicular processes that bring matter into a cell are called **endocytosis**²⁶ (EN-doe-sy-TOE-sis) and those that release material from a cell are called **exocytosis**²⁷ (EC-so-sy-TOE-sis). These processes employ motor proteins whose movements are energized by ATP.

There are three forms of endocytosis: phagocytosis, pinocytosis, and receptor-mediated endocytosis. **Phagocytosis**²⁸ (FAG-oh-sy-TOE-sis), or “cell eating,” is the process of engulfing particles such as bacteria, dust, and cellular debris—particles large enough to be seen with a microscope. For example, neutrophils (a class of white blood cells) protect the body from infection by phagocytizing and killing bacteria. A neutrophil spends most of its life crawling about in the connective tissues by means of its pseudopods. When a neutrophil encounters a bacterium, it surrounds it with pseudopods and traps it in a vesicle called a **phagosome**²⁹—a vesicle in the cytoplasm surrounded by a membrane (**fig. 3.20**). A lysosome merges with the phagosome, converting it to a *phagolysosome*, and contributes enzymes that destroy the invader. Some other kinds of phagocytic cells are described in chapter 21. In general, phagocytosis is a way of keeping the tissues free of debris and infectious microbes. Some cells called *macrophages* (literally, “big eaters”) phagocytize the equivalent of 25% of their own volume per hour.

Pinocytosis³⁰ (PIN-oh-sy-TOE-sis), or “cell drinking,” is the process of taking in droplets of ECF containing molecules of some use to the cell. While phagocytosis occurs in only a few specialized cells, pinocytosis occurs in all human cells. The process begins as the plasma membrane dimples, or caves in, at points. These pits soon separate from the surface membrane and form small membrane-bounded **pinocytotic vesicles** in the cytoplasm. The vesicles contain droplets of the ECF with whatever molecules happen to be there.

Receptor-mediated endocytosis (**fig. 3.21**) is a more selective form of either phagocytosis or pinocytosis. It enables a cell to take in specific molecules from the ECF with a minimum of unnecessary matter. Particles in the ECF bind to specific receptors on the plasma membrane. The receptors then cluster and the membrane sinks in at this point, creating a pit coated with a peripheral membrane protein called *clathrin*.³¹ The pit soon pinches off to form a *clathrin-coated vesicle* in the cytoplasm. Clathrin may serve as an “address label” on the coated vesicle that directs it to an appropriate destination in the cell, or it may inform other structures in the cell what to do with the vesicle.

One example of receptor-mediated endocytosis is the uptake of *low-density lipoproteins (LDLs)*—protein-coated droplets of cholesterol and other lipids in the blood. The thin endothelial cells that line our blood vessels have LDL receptors on their surfaces and absorb LDLs in clathrin-coated vesicles. Inside the cell, the LDL is freed from the vesicle and metabolized, and the membrane with its receptors is recycled to the cell surface.

Endothelial cells also imbibe insulin by receptor-mediated endocytosis. Insulin is too large to pass through channels in the plasma membrane, yet it must somehow get out of the blood and reach the surrounding cells if it is to have any effect. Endothelial cells take up insulin by receptor-mediated endocytosis, transport

²⁶endo = into; cyt = cell; osis = process

the vesicles across the cell, and release the insulin on the other side, where tissue cells await it. Such transport of material across a cell (capture on one side and release on the other) is called **transcytosis**³² (fig. 3.22). This process is especially active in muscle capillaries and transfers a significant amount of blood albumin into the tissue fluid.

Receptor-mediated endocytosis isn't always to our benefit; hepatitis, polio, and AIDS viruses trick our cells into engulfing them by receptor-mediated endocytosis, thus exploiting this mechanism to establish infection.

Exocytosis (fig. 3.23) is a process of discharging material from a cell. It occurs, for example, when endothelial cells release insulin to the tissue fluid, sperm cells release enzymes for penetrating an egg, mammary gland cells secrete milk sugar, and other gland cells release hormones. It bears a superficial resemblance to endocytosis in reverse. A secretory vesicle in the cell migrates to the surface and “docks” on peripheral proteins of the plasma membrane. These proteins pull the membrane inward and create a dimple that eventually fuses with the vesicle and allows it to release its contents.

The question might occur to you, If endocytosis continually takes away bits of plasma membrane to form intracellular vesicles, why doesn't the membrane grow smaller and smaller? Another purpose of exocytosis, however, is to replace plasma membrane that has been removed by endocytosis or that has become damaged or worn out. Empty vesicles are transported to the inner surface of the plasma membrane and fuse with it. Exocytosis must keep pace with the rate of membrane removal by endocytosis, or else a cell would shrivel and die. Plasma membrane is continually recycled from the cell surface into the cytoplasm and back to the surface.

Table 3.3 summarizes these mechanisms of transport.

FIGURE 3.22 Transcytosis. An endothelial cell of a capillary imbibes droplets of blood plasma at sites indicated by arrows along the left. This forms pinocytotic vesicles, which the cell transports to the other side. Here, it releases the contents by exocytosis at sites indicated by arrows along the right side of the cell.

Don Fawcett/Science Source

? Why isn't transcytosis listed as a separate means of membrane transport, in addition to pinocytosis and the others?

³²trans = across; cyt = cell; osis = process

TABLE 3.3 Methods of Membrane Transport

Transport Without Carriers	Movement of Material Without the Aid of Carrier Proteins
Filtration	Movement of water and solutes through a selectively permeable membrane as a result of hydrostatic pressure
Simple diffusion	Diffusion of particles through water or air or through a living or artificial membrane, down their concentration gradient, without the aid of membrane carriers
Osmosis	Net flow of water through a selectively permeable membrane, driven by either a difference in solute concentration or a mechanical force
Carrier-Mediated Transport	Movement of Material Through a Cell Membrane by Carrier Proteins
Facilitated diffusion	Transport of particles through a selectively permeable membrane, down their concentration gradient, by a carrier that does not directly consume ATP
Primary active transport	Transport of solute particles through a selectively permeable membrane, up their concentration gradient, by a carrier that consumes ATP
Secondary active transport	Transport of solute particles through a selectively permeable membrane, up their concentration gradient, by a carrier that doesn't use ATP itself but depends on concentration gradients produced by primary active transport elsewhere in the membrane
Cotransport	Simultaneous transport of two or more solutes in the same direction through a membrane by a carrier protein called a <i>symport</i> , using either facilitated diffusion or active transport
Countertransport	Transport of two or more solutes in opposite directions through a membrane by a carrier protein called an <i>antiport</i> , using either facilitated diffusion or active transport
Vesicular (Bulk) Transport	Movement of Fluid and Particles Through a Plasma Membrane by Way of Membrane Vesicles; Consumes ATP
Endocytosis	Vesicular transport of particles into a cell
Phagocytosis	Process of engulfing large particles by means of pseudopods; "cell eating"
Pinocytosis	Process of imbibing extracellular fluid in which the plasma membrane sinks in and pinches off small vesicles containing droplets of fluid; "cell drinking"
Receptor-mediated endocytosis	Phagocytosis or pinocytosis in which specific solute particles bind to receptors on the plasma membrane, and are then taken into the cell in clathrin-coated vesicles with a minimal amount of extraneous matter
Exocytosis	Process of eliminating material from a cell by means of a vesicle approaching the cell surface, fusing with the plasma membrane, and expelling its contents; used to release cell secretions, replace worn-out plasma membrane, and replace membrane that has been internalized by endocytosis

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- What is the importance of filtration to human physiology?
- What does it mean to say a solute moves down its concentration gradient?
- How does osmosis help to maintain blood volume?
- Define *osmolarity* and *tonicity*, and explain the difference between them.
- Define *hypotonic*, *isotonic*, and *hypertonic*, and explain why these concepts are important in clinical practice.
- What do facilitated diffusion and active transport have in common? How are they different?
- How does the $\text{Na}^+ - \text{K}^+$ pump exchange sodium ions for potassium ions across the plasma membrane? What are some purposes served by this pump?
- How does phagocytosis differ from pinocytosis?
- Describe the process of exocytosis. What are some of its purposes?

3.4 The Cell Interior**Expected Learning Outcomes**

When you have completed this section, you should be able to

- describe the cytoskeleton and its functions;
- list the main organelles of a cell, describe their structure, and explain their functions; and
- give some examples of cell inclusions and explain how inclusions differ from organelles.

We now probe more deeply into the cell to study its internal structures. These are classified into three groups—*cytoskeleton*, *organelles*, and *inclusions*—all embedded in the cytosol.

3.4a The Cytosol and Cytoskeleton

The **cytosol** is a clear, viscous, watery colloid that bathes the cytoskeleton and organelles. It contains enzymes, other proteins, amino acids, ATP, electrolytes, other diverse organic and inorganic ions, oxygen, carbon dioxide, and metabolic wastes. It is the site of glycolysis, anaerobic fermentation, and most protein synthesis.

The **cytoskeleton** is a network of protein filaments and cylinders that structurally support a cell, determine its shape, organize its contents, direct the movement of materials within the cell, and contribute to movements of the cell as a whole. It forms a dense supportive scaffold in the cytoplasm (**fig. 3.24**). It is connected to transmembrane proteins of the plasma membrane, and they in turn are connected to protein fibers external to the cell, creating a strong structural continuity from extracellular material to the cytoplasm. Cytoskeletal elements even connect to chromosomes in the nucleus, enabling physical tension on a cell to move nuclear contents, mechanically stimulate genetic function, and influence the timing of cell division relative to cell size.

The cytoskeleton is composed of *microfilaments*, *intermediate filaments*, and *microtubules*. If you think of intermediate filaments as being like the stiff rods of uncooked spaghetti, you could, by comparison, think of microfilaments as being like fine angel-hair pasta and microtubules like tubular penne pasta.

Microfilaments (thin filaments) are about 6 nm thick and are made of the protein *actin*. They are widespread throughout the cell but especially concentrated in a fibrous mat called the **terminal web (membrane skeleton)** on the cytoplasmic side of the plasma membrane. The phospholipids of the plasma membrane spread out over the terminal web like butter on a slice of bread. The web, like the bread, provides physical support, whereas the lipids, like butter, provide a permeability barrier. It is thought that without the support of the terminal web, the phospholipids would break up into little droplets and the plasma membrane wouldn't hold together. As described earlier, actin microfilaments also form the supportive cores of the microvilli and play a role in cell movement. Through its role in cell motility, actin plays a crucial role in embryonic development, muscle contraction, immune function, wound healing, cancer metastasis, and other processes that involve cell migration.

Intermediate filaments (8–10 nm thick) are thicker and stiffer than microfilaments. They give the cell its shape, resist stress, and form junctions that attach cells to their neighbors. In epidermal cells, they are made of the tough protein *keratin* and occupy most of the cytoplasm. They are responsible for the strength of hair and fingernails.

Microtubules (25 nm in diameter) are cylinders made of 13 parallel strands called *protofilaments*. Each protofilament is a long chain of globular proteins called *tubulin* (**fig. 3.25**). Microtubules radiate from an area of the cell called the *centrosome*. They hold organelles in place, form bundles that maintain cell shape and rigidity, and act like monorail tracks for motor proteins carrying organelles and macromolecules to specific destinations in the cell. Microtubules form the axonemes of cilia and flagella and are responsible for their beating movements, and form the mitotic spindle that guides chromosome movement during cell division. Microtubules aren't permanent structures. They come and go moment by moment as tubulin molecules assemble into a tubule and

then break apart again to be used somewhere else in the cell. The microtubules in cilia, flagella, basal bodies, and centrioles, however, are more stable.

3.4b Organelles

Organelles (literally, “little organs”) are to the cell what organs are to the body—structures that play individual physiological roles in the survival of the whole. There is no universally agreed definition of the word *organelle*. Some authorities include cilia, microvilli, and even the plasma membrane in this concept, whereas others exclude intracellular structures such as ribosomes and centrioles because they're not enclosed in membranes. This book, however, regards organelles as the intracellular structures, above the molecular level of complexity, that play indispensable roles in cellular metabolism. Some organelles are surrounded by membranes and are therefore referred to as *membranous organelles*. These are the nucleus, mitochondria, lysosomes, peroxisomes, endoplasmic reticulum, and Golgi complex. Organelles without membranes include ribosomes, proteasomes, centrosomes, centrioles, and basal bodies.

The Nucleus

The **nucleus** (**fig. 3.26**) is usually the largest organelle and the only one clearly visible with the light microscope. It contains the cell's chromosomes and is therefore the genetic control center of cellular activity. It is typically spheroidal to elliptical in shape and about 5 μm in diameter. Most cells have a single nucleus, but there are exceptions. Mature red blood cells have none; they are **anuclear**. A few cell types are **multinuclear**. Many cells of the liver, urinary bladder, and heart have two nuclei; bone-dissolving cells called osteoclasts have as many as 50; and a single skeletal muscle cell can have many thousands.

Figure 3.27 shows the details of nuclear structure. The nucleus is enclosed in a double membrane, the **nuclear envelope**. The envelope is perforated with **nuclear pores** formed by a ring of proteins called the *nuclear pore complex*. These proteins regulate molecular traffic through the envelope and act like a rivet to hold the two membrane layers together. Hundreds of molecules pass through the nuclear pores every minute. Coming into the nucleus are raw materials for DNA and RNA synthesis, enzymes that are made in the cytoplasm but function in the nucleus, and hormones and other chemical messengers that activate certain genes. Going the other way, RNA is made in the nucleus but leaves to perform its job in the cytoplasm.

Immediately inside the nuclear envelope is a narrow but densely fibrous zone called the **nuclear lamina**, composed of a web of intermediate filaments. It supports the nuclear envelope and pores, provides points of attachment and organization for the chromosomes inside the nucleus, and plays a role in regulating DNA replication and the cell life cycle. Abnormalities of its structure or function are associated with certain genetic diseases and premature cell death.

The material in the nucleus is called **nucleoplasm**. This includes **chromatin**³³ (CRO-muh-tin)—fine threadlike matter composed of DNA and protein—and one or more dark-staining

³³chromat = colored; in = substance

FIGURE 3.24 The Cytoskeleton. (a) Components of the cytoskeleton. Few organelles are shown in order to emphasize the cytoskeleton. (b) One of the nine microtubule pairs that form the axonemes of cilia and flagella, with the motor protein dynein attached. (c) One of the nine microtubule triplets that form a centriole.

FIGURE 3.27 Structure of the Nucleus. (a) Cutaway view showing the nuclear surface and contents of the nucleoplasm. (b) Detail of a nuclear pore complex.

? Why do these nuclear pores have to be larger in diameter than the channels in the cell's plasma membrane? (See table 3.1.)

masses called **nucleoli** (singular, *nucleolus*), where ribosomes are produced. The genetic function of the nucleus is described in the next chapter.

Endoplasmic Reticulum

Endoplasmic reticulum (ER) literally means “little network within the cytoplasm.” It is a system of interconnected channels

FIGURE 3.26 The Nucleus as Seen by Electron Microscopy. These photomicrographs were made by different TEM methods to show the internal structure of the nucleus and surface of the nuclear envelope. (a) Interior of the nucleus. (b) Surface of the nucleus, showing clusters of nuclear pores.

a: Jose Luis Calvo/Shutterstock; b: Don Fawcett/Science Source

called **cisterns**³⁴ enclosed by a unit membrane (**fig. 3.28**). In areas called **rough endoplasmic reticulum**, the cisterns are parallel, flattened sacs covered with granules called *ribosomes*. Adjacent cisterns are connected by bridges to create one continuous internal space. The rough ER is continuous with the outer membrane of the nuclear envelope, and some authorities regard the nuclear envelope as simply a modified extension of it. In areas called **smooth endoplasmic reticulum**, the cisterns are more tubular, branch more extensively, and lack ribosomes. The cisterns of the smooth ER are continuous with those of the rough ER, so the two are different parts of the same network.

The ER synthesizes steroids and other lipids, detoxifies alcohol and other drugs, and manufactures nearly all membranes of the cell. Rough ER produces the phospholipids and proteins of the plasma membrane and synthesizes proteins that are either secreted from the cell or packaged in organelles such as lysosomes. Rough ER is most abundant in cells that synthesize large amounts of protein, such as antibody-producing cells and cells of the digestive glands. In such cells, the ER is often the largest organelle of all, although it isn't visible to the light microscope (LM) because its thin and closely spaced membranes are beyond the LM's limit of resolution.

Most cells have only a scanty smooth ER, but it's relatively abundant in cells that engage extensively in detoxification, such as liver and kidney cells. Long-term abuse of alcohol, barbiturates, and other drugs leads to tolerance partly because the smooth ER

³⁴cistern = reservoir

proliferates and detoxifies the drugs more quickly. Smooth ER is also abundant in cells of the testes and ovaries that synthesize steroid hormones. Skeletal and cardiac muscle contain extensive networks of smooth ER that store calcium and release it to trigger muscle contraction.

Ribosomes

Ribosomes are small granules of protein and RNA found in the nucleoli, in the cytosol, in mitochondria, and on the outer surfaces of the rough ER and nuclear envelope. They “read” coded genetic messages (messenger RNA) and assemble amino acids into proteins specified by the code. The unattached ribosomes scattered throughout the cytoplasm make enzymes and other proteins for use within the cell. Free ribosomes within the nucleus and mitochondria make proteins for use in those organelles. Ribosomes attach to the rough ER when they make proteins destined to be packaged in lysosomes or to be secreted from the cell, such as digestive enzymes, antibodies, and some hormones.

Golgi Complex

The **Golgi**³⁵ **complex** (GOAL-jee) is a small system of cisterns that synthesize carbohydrates and put the finishing touches on protein and glycoprotein synthesis. The complex resembles a stack of pita bread. It consists of only a few cisterns, slightly separated from each other; each cistern is a flattened, often curved sac with swollen edges (**fig. 3.29**). The Golgi complex

FIGURE 3.29 The Golgi Complex.

Science History Images/Alamy Stock Photo

³⁵Camillo Golgi (1843–1926), Italian histologist

receives newly synthesized proteins from the rough ER. It sorts them, cuts and splices some of them, and adds carbohydrate to some. Finally, the most mature cistern with the finished cell product breaks up into membrane-bounded **Golgi vesicles**, which are abundant in the neighborhood of the Golgi complex. Some vesicles become *lysosomes*, the organelle discussed next; some migrate to the plasma membrane and fuse with it, contributing fresh protein and phospholipid to the membrane; and some become **secretory vesicles** that store a cell product, such as breast milk or digestive enzymes, for later release. The roles of the endoplasmic reticulum, ribosomes, and Golgi complex in protein synthesis and secretion are detailed in chapter 4.

Lysosomes

A **lysosome**³⁶ (LY-so-some) (**fig. 3.30**) is a package of enzymes bounded by a membrane. Although often round or oval, lysosomes vary in shape. When viewed with the TEM, they often exhibit dark gray contents devoid of structure, but sometimes show crystals or parallel layers of protein. At least 50 lysosomal enzymes have been identified. They hydrolyze proteins, nucleic acids, complex

FIGURE 3.30 Lysosome and Peroxisome. Each is bounded by a membrane similar to the plasma membrane, but they contain different enzymes with different functions.

EM Research Services, Newcastle University

³⁶*lyso* = loosen, dissolve; *some* = body

carbohydrates, phospholipids, and other substrates. In the liver, lysosomes break down glycogen to release glucose into the bloodstream. White blood cells use lysosomes to digest phagocytized bacteria. Lysosomes also digest and dispose of surplus or nonvital organelles and other cell components in order to recycle their nutrients to more important cell needs; this process is called **autophagy**³⁷ (aw-TOFF-uh-jee). Lysosomes also aid in a process of “cell suicide.” Some cells are meant to do a certain job and then destroy themselves. The uterus, for example, weighs about 900 g at full-term pregnancy and shrinks to 60 g within 5 or 6 weeks after birth. This shrinkage is due to **autolysis**,³⁸ the digestion of surplus cells by their own lysosomal enzymes.

Peroxisomes

Peroxisomes (fig. 3.30) resemble lysosomes but contain different enzymes. They are produced by collaboration between the endoplasmic reticulum and mitochondria and by fission of preexisting peroxisomes. Their general function is to use molecular oxygen (O_2) to oxidize organic molecules. These reactions produce hydrogen peroxide (H_2O_2)—hence, the name of the organelle. H_2O_2 is then used to oxidize other molecules, and the excess is broken down to water and oxygen by an enzyme called *catalase*.

Peroxisomes occur in nearly all cells but are especially abundant in liver and kidney cells. They neutralize free radicals and detoxify alcohol, other drugs, and a variety of blood-borne toxins. Peroxisomes also decompose fatty acids into two-carbon fragments that the mitochondria use as an energy source for ATP synthesis.

Proteasomes

Cells must tightly control the concentration of proteins in their cytoplasm. Therefore, they must not only synthesize new proteins, but also dispose of those no longer needed. Cells also need to rid themselves of damaged and nonfunctional proteins and foreign proteins introduced by such events as viral infection. Protein synthesis, we have seen, is the domain of the ribosomes; protein disposal is the function of another structurally simple organelle called a **proteasome**.

Proteasomes are hollow, cylindrical complexes of proteins located in both the cytoplasm and nucleus (**fig. 3.31**). A cell tags undesirable proteins for destruction and transports them to a proteasome. As the undesirable protein passes through the core of this organelle, the proteasome’s enzymes unfold it and break it down into short peptides and free amino acids. These can be used to synthesize new proteins or be presented to the immune system for action. Proteasomes degrade more than 80% of a cell’s proteins.

Mitochondria

Mitochondria³⁹ (MY-toe-CON-dree-uh) (singular, *mitochondrion*) are organelles specialized for synthesizing ATP. They have a variety of shapes—spheroidal, rod-shaped, kidney-shaped, or

FIGURE 3.31 Protein Degradation by a Proteasome.

(a) The unwanted protein targeted for destruction is tagged and transported to a proteasome. (b) As the protein passes down the core of the proteasome, it is unfolded and cleaved into small peptides and free amino acids. (c) The degraded protein fragments are released from the other end of the proteasome.

threadlike (**fig. 3.32**). They are quite mobile, squirming and changing shape continually. They sometimes undergo fusion (two mitochondria joining to become one) and fission (one mitochondrion dividing in two). Like the nucleus, a mitochondrion is surrounded by a double membrane. The inner membrane usually has folds called **cristae**⁴⁰ (CRIS-tee), which project like shelves across the organelle. The space between the cristae, called the **matrix**, contains ribosomes; enzymes used in ATP synthesis; and a few small, circular DNA molecules called *mitochondrial DNA (mtDNA)*.

The principal function of mitochondria is to serve as the “powerhouses” of the cell. Energy isn’t *made* here, but it is extracted from organic compounds and transferred to ATP, primarily by enzymes located on the cristae. The role of mitochondria in ATP synthesis is explained in detail in chapter 26. Liver mitochondria also play a role in detoxifying ammonia (a waste product of protein metabolism) and in converting amino acids and other organic molecules to glucose. Some evolutionary and clinical aspects of mitochondria are discussed in Deeper Insight 3.3.

⁴⁰crista = crest

FIGURE 3.32 A Mitochondrion.

a: Scott Camazine/Alamy Stock Photo;

Centrioles

A **centriole** (SEN-tree-ole) is a short cylindrical assembly of microtubules, arranged in nine groups of three microtubules each (**fig. 3.33**). Near the nucleus, most cells have a small, clear patch of cytoplasm called the **centrosome**⁴¹ containing a pair of mutually perpendicular centrioles (**see fig. 3.24**). Centrioles play a role in cell division described in the next chapter. Each basal body of a flagellum or cilium is a single centriole oriented perpendicular to the plasma membrane. Basal bodies originate in a *centriolar organizing center* and migrate to the plasma membrane. Two microtubules of each triplet then elongate to form the nine pairs of peripheral microtubules of the axoneme. A cilium can grow to its full length in less than an hour.

3.4c Inclusions

Inclusions are of two kinds: accumulated cell products such as glycogen granules, pigments, and oil droplets (**see fig. 3.28b**); and foreign bodies such as viruses, bacteria, and dust particles and other debris phagocytized by a cell. Inclusions are never enclosed in a membrane, and unlike the organelles and cytoskeleton, they are not essential to cell survival.

⁴¹*centro* = central; *some* = body

DEEPER INSIGHT 3.3

EVOLUTIONARY MEDICINE

Mitochondria—Evolution and Clinical Significance

It is virtually certain that mitochondria evolved from bacteria that invaded another primitive cell, survived in its cytoplasm, and became permanent residents. The double membranes around the mitochondrion suggest that the original bacterium provided the inner membrane, and the host cell's phagosome provided the outer membrane when the bacterium was phagocytized.

Several comparisons show the apparent relationship of mitochondria to bacteria. Their ribosomes are more like bacterial ribosomes than those of eukaryotic (nucleated) cells. Mitochondrial DNA (mtDNA) is a small, circular molecule that resembles the circular DNA of bacteria, not the linear DNA of the cell nucleus. It replicates independently of nuclear DNA. Mitochondrial DNA codes for some of the enzymes employed in ATP synthesis. It consists of 16,569 *base pairs* (explained in chapter 4), comprising 37 genes, compared with over 3 billion base pairs and over 22,000 genes in nuclear DNA.

When a sperm fertilizes an egg, any mitochondria introduced by the sperm are destroyed and only those provided by the egg are passed on to the developing embryo. Therefore, mtDNA is inherited exclusively through the mother. While nuclear DNA is reshuffled in every generation by sexual reproduction, mtDNA remains unchanged except by random mutation. Because of the known pace of such mutations, biologists and anthropologists can use mtDNA as a “molecular clock” to trace evolutionary lineages in humans and other species. The amount of difference between the mtDNAs of related species affords a record of how much time has passed since they diverged from their last common ancestor. Anthropologists have gained evidence from mtDNA that of all the females who lived in Africa 200,000 years ago, only one has left an unbroken line of female descent to today. Other females from that time, however, may have descendants alive today through sons and the subsequent male line. (Similarly, all males living today are thought to be

descended from a single male who lived about 300,000 years ago. This was traced not through mtDNA, of course, but through the Y chromosome.) Mitochondrial DNA has also been used as evidence in criminal law and to identify the remains of soldiers killed in combat. It was used in 2001 to identify the remains of the famed bandit Jesse James, who was killed in 1882.

Mutations in mtDNA are responsible for various rare hereditary diseases and death in early childhood. Tissues and organs with the highest energy demands are the most vulnerable to mitochondrial dysfunctions—nervous tissue, the heart, the kidneys, and skeletal muscles, for example.

Mitochondrial myopathy is a degenerative muscle disease in which the muscle displays “ragged red fibers,” cells with abnormal mitochondria that stain red with a particular histological stain. Another mtDNA disease is *Leber hereditary optic neuropathy (LHON)*, a form of blindness that usually appears in young adulthood as a result of damage to the optic nerve. *Kearns–Sayre syndrome (KSS)* involves paralysis of the eye muscles, degeneration of the retina, heart disease, hearing loss, diabetes, and kidney failure. Damage to mtDNA has also been implicated as a possible factor in Alzheimer disease, Huntington disease, and other degenerative diseases of old age.

Some women known to carry mtDNA mutations can now avoid passing such diseases to their children through in vitro fertilization (IVF) with mitochondrial replacement therapy (MRT). The techniques of MRT are complex and diverse, but the essence of it is to provide an egg of the patient with healthy mitochondria from another egg donor; fertilize the recipient egg with the father's sperm; and implant this in the patient's uterus. The successful result is a “three-parent baby” who has the father's nuclear DNA, the birth mother's nuclear DNA, and the mitochondria donor's mtDNA.

FIGURE 3.33 Centrioles. (a) Electron micrograph of a centriole as seen in cross section. (b) A pair of perpendicular centrioles.

? How does a centriole resemble the axoneme of a cilium? How does it differ?

a: Don W. Fawcett/Science Source

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

22. Distinguish between organelles and inclusions. State two examples of each.
23. Briefly state how each of the following cell components can be recognized in electron micrographs: the nucleus, a mitochondrion, a lysosome, and a centriole. What is the primary function of each?
24. What three organelles are involved in protein synthesis?
25. In what ways do rough and smooth endoplasmic reticulum differ?
26. Define *centriole*, *microtubule*, *cytoskeleton*, and *axoneme*. How are these structures related to one another?

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

3.1 Concepts of Cellular Structure

1. The scope of cytology
2. Basic tenets of the cell theory
3. The nine common cell shapes

4. The size range of most human cells; some extremes outside this range; and some factors that limit cells from growing indefinitely large
5. The two kinds of electron microscopes; why they have enhanced the modern understanding of cells; and the distinction between magnification and resolution in microscopy

6. Basic structural components of a cell
7. The distinction between intracellular fluid (ICF) and extracellular fluid (ECF)

3.2 The Cell Surface

1. The molecules of the plasma membrane and how they are organized

STUDY GUIDE

- The distinctive roles of phospholipids, glycolipids, cholesterol, integral proteins, peripheral proteins, and glycoproteins in membrane structure
- Seven roles played by membrane proteins
- Distinctions between leak channels and gated channels, and between ligand-gated, voltage-gated, and mechanically gated channels
- The function of second-messenger systems associated with the plasma membrane; the specific roles of membrane receptors, G proteins, adenylate cyclase, cyclic adenosine monophosphate, and kinases in the cAMP second-messenger system
- Composition and functions of the glycocalyx
- Structure and functions of microvilli, and where they are found
- Structure and functions of cilia, and where they are found
- Structure and function of the only human flagellum
- Structure and function of pseudopods

3.3 Membrane Transport

- What it means to say that a plasma membrane is selectively permeable, and why this property is important for human survival
- Filtration, where it occurs in the body, and why it depends on hydrostatic pressure
- Simple diffusion, factors that determine its speed, and examples of its physiological and clinical relevance
- Osmosis, examples of its physiological and clinical relevance, factors that determine its speed and direction, and the role of aquaporins

- Reverse osmosis, where it occurs in the body, and the purpose it serves
- In relation to osmosis, the meaning of *osmotic pressure*, *osmolarity*, *tonicity*, and *milliosmoles per liter (mOsm/L)*
- Distinctions between hypotonic, hypertonic, and isotonic solutions; their effects on cells; and how this relates to intravenous fluid therapy
- How carrier-mediated transport differs from other types of transport, and the relevance of specificity to this process
- How carrier-mediated transport is limited by carrier saturation and the transport maximum (T_m)
- Distinctions between a uniport, symport, and antiport; the meanings of *cotransport* and *countertransport*; and examples of where each is relevant in human physiology
- Similarities and differences between facilitated diffusion and active transport
- The distinction between primary and secondary active transport
- The mechanism and roles of the sodium–potassium (Na^+/K^+) pump
- How vesicular transport differs from other modes of membrane transport; the difference between endocytosis and exocytosis; different forms of endocytosis; and examples of the physiological relevance of each kind of vesicular transport
- Of the preceding mechanisms of transport, which ones require a membrane; which ones can also occur through artificial membranes;

which ones require ATP and cease if ATP is unavailable, as upon death

3.4 The Cell Interior

- Distinctions between cytoplasm, cytosol, cytoskeleton, organelles, and inclusions; and the respective, general roles of each in the internal organization of a cell
- Overall functions of the cytoskeleton and the differences between microfilaments, intermediate filaments, and microtubules
- Which organelles are considered membranous and why, and which of these are enclosed in single or double membranes
- Structure and function of the nucleus, especially the nuclear envelope and nuclear lamina
- General structure of the endoplasmic reticulum (ER); the two types of ER and the structural and functional differences between them
- The composition, location, and function of ribosomes
- The structure and functions of the Golgi complex; the origin and destiny of Golgi vesicles
- The structures and functions of lysosomes and peroxisomes, and the similarities and differences between them
- Structure and function of proteasomes
- Structure and function of mitochondria
- Structures and functions of centrioles, the centrosome, and basal bodies; and how these relate to each other
- How inclusions differ from organelles; the origins and types of inclusions

▶ Testing Your Recall

Answers in Appendix A

- The clear, structureless gel in a cell is its
 - nucleoplasm.
 - protoplasm.
 - cytoplasm.
 - neoplasm.
 - cytosol.
- The Na^+/K^+ pump is
 - a peripheral protein.
 - a transmembrane protein.
 - a G protein.
 - a glycolipid.
 - a phospholipid.
- Which of the following processes could occur *only* in the plasma membrane of a living cell?
 - facilitated diffusion
 - simple diffusion
 - filtration
 - active transport
 - osmosis
- Cells specialized for absorption of matter from the ECF are likely to show an abundance of
 - lysosomes.
 - microvilli.
 - mitochondria.
 - secretory vesicles.
 - ribosomes.
- Aquaporins are transmembrane proteins that promote
 - pinocytosis.
 - carrier-mediated transport.
 - active transport.
 - facilitated diffusion.
 - osmosis.
- Membrane carriers resemble enzymes except for the fact that carriers
 - are not proteins.
 - do not have binding sites.
 - are not selective for particular ligands.
 - change conformation when they bind a ligand.
 - do not chemically change their ligands.

STUDY GUIDE

7. The cotransport of glucose derives energy from
 - a. a Na^+ concentration gradient.
 - b. the glucose being transported.
 - c. a Ca^{2+} gradient.
 - d. the membrane voltage.
 - e. body heat.
8. The function of cAMP in a cell is
 - a. to activate a G protein.
 - b. to remove phosphate groups from ATP.
 - c. to activate kinases.
 - d. to bind to the first messenger.
 - e. to add phosphate groups to enzymes.
9. Most cellular membranes are made by
 - a. the nucleus.
 - b. the cytoskeleton.
 - c. enzymes in the peroxisomes.
 - d. the endoplasmic reticulum.
 - e. replication of existing membranes.
10. Matter can leave a cell by any of the following means *except*
 - a. active transport.
 - b. pinocytosis.
 - c. an antiport.
 - d. simple diffusion.
 - e. exocytosis.
11. Most human cells are 10 to 15 _____ in diameter.
12. When a hormone cannot enter a cell, it activates the formation of a/an _____ inside the cell.
13. _____ channels in the plasma membrane open or close in response to changes in the electrical charge difference across the membrane.
14. The force exerted on a membrane by water is called _____.
15. A concentrated solution that causes a cell to shrink is _____ to the cell.
16. Fusion of a secretory vesicle with the plasma membrane and release of the vesicle's contents is a process called _____.
17. _____ and _____ are two granular organelles (enzyme complexes) that, respectively, synthesize and degrade proteins.
18. Liver cells can detoxify alcohol with two organelles, the _____ and _____.
19. An ion gate in the plasma membrane that opens or closes when a chemical binds to it is called a/an _____.
20. The space enclosed by the membranes of the Golgi complex and endoplasmic reticulum is called the _____.

▶ Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|--------------|-----------|------------|
| 1. anti- | 3. co- | 7. fusi- |
| 2. chromato- | 4. cyto- | 8. -logy |
| | 5. endo- | 9. -osis |
| | 6. facil- | 10. phago- |

▶ What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. If a cell were poisoned so it could not make ATP, osmosis through its membrane would cease.
2. Each cell of the human body has a single nucleus.
3. A cell's second messengers serve mainly to transport solutes through the membrane.
4. The Golgi complex makes all of a cell's lysosomes and peroxisomes.
5. Some membrane channels are peripheral proteins.
6. The plasma membrane consists primarily of protein molecules.
7. The brush border of a cell is composed of cilia.
8. Human cells placed in hypertonic saline will swell and burst.
9. The transport maximum (T_m) sets an upper limit on the rate of osmosis.
10. All of a cell's ribosomes are found on the nuclear envelope and the rough endoplasmic reticulum.

▶ Testing Your Comprehension

1. If someone bought a saltwater fish in a pet shop and put it in a freshwater aquarium at home, what would happen to the fish's cells? What would happen if someone put a freshwater fish in a saltwater aquarium? Explain.
2. A farmer's hand and forearm are badly crushed in a hay baler. When examined at the hospital, his blood potassium level is found to be abnormal. Would you expect it to be higher or lower than normal? Explain.
3. Many children worldwide suffer from a severe deficiency of dietary protein. As a result, they have very low levels of blood albumin. How do you think this affects the water content and volume of their blood? Explain.
4. It is often said, even in some textbooks, that mitochondria make energy for a cell. Why is this statement false?
5. Kartagener syndrome is a hereditary disease in which dynein arms are lacking from the axonemes of cilia and flagella. Predict the effect of Kartagener syndrome on a man's ability to father a child. Predict its effect on his respiratory health. Explain both answers.

Module 2: Cells and Chemistry

BRUSHING UP

- To understand how genes direct the synthesis of proteins, you must be familiar with protein structure (see section 2.4e).
- Understanding the processing and packaging of proteins depends on familiarity with the organelles that carry out these processes (see section 3.4b).
- Brush up on exocytosis (see section 3.3f) to understand how a cell secretes newly synthesized proteins made for use outside the cell.
- Be sure you are familiar with microtubules and centrioles, both in section 3.4a, as a basis for understanding cell division by mitosis.

Several chapters in this book discuss hereditary traits such as blood types and hair color and genetic disorders such as color blindness, cystic fibrosis, diabetes mellitus, and hemophilia. To understand such conditions, it is necessary to have some familiarity with DNA and genes. This chapter is intended to provide such preparation.

Heredity has been a matter of human interest dating even to biblical writings, but a scientific understanding of how traits pass from parents to offspring began with the Austrian monk Gregor Mendel (1822–84) and his famous experiments on garden peas. By the late nineteenth century, biologists had observed chromosomes and their behavior during cell division. In the early twentieth century, they rediscovered Mendel's work and realized the correlation between chromosome behavior and his laws of heredity. From that simple but insightful beginning, genetics has grown into a highly diverse science with several subdisciplines and is arguably the most dynamic of all natural sciences in these early decades of the twenty-first century.

Mendelian genetics deals with parent–offspring and larger family relationships to discern and predict patterns of inheritance within a family line. *Cytogenetics* uses the techniques of cytology and microscopy to study chromosomes and their relationship to hereditary traits. *Molecular genetics* uses the techniques of biochemistry to study the structure and function of DNA. *Genomic medicine* comprehensively studies the entire DNA endowment of an individual (the *genome*), how it influences health and disease, and how this knowledge can be used to prevent, treat, or cure diseases. We will examine these perspectives in this chapter.

4.1 DNA and RNA—The Nucleic Acids

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the structure of DNA and relate this to its function;
- explain how DNA and proteins are organized to form the chromosomes; and
- describe the types of RNA, their structural and functional differences, and how they compare with DNA.

With improvements in the microscope, biologists of the late nineteenth century saw that cell division is immediately preceded by nuclear division, and during nuclear division, the chromosomes split neatly in two and distribute their halves to the two daughter cells. They came to suspect that the nucleus was the center of heredity and cellular control, and they began probing it for the biochemical secrets of heredity. Swiss biochemist Johann Friedrich Miescher (1844–95) studied the nuclei of white blood cells extracted from pus in hospital bandages, and later the nuclei of salmon sperm, since both cell types offered large nuclei with minimal amounts of contaminating cytoplasm. In 1869, he discovered an acidic, phosphorus-rich substance he named *nuclein*. He correctly believed this to be the cell's hereditary matter, although he was never able to convince other scientists of this. We now call this substance **deoxyribonucleic acid (DNA)** and know it to be the repository of our genes.

By 1900, biochemists knew the basic components of DNA—sugar, phosphate groups, and organic rings called nitrogenous bases—but they didn't have the technology to determine how these were put together. That understanding didn't come until 1953, in one of the twentieth century's most dramatic and important stories of scientific discovery (see Deeper Insight 4.1). The following description of DNA is largely the outcome of that work.

4.1a DNA Structure and Function

DNA is a long threadlike molecule with a uniform diameter of 2 nm, although its length varies greatly from the smallest to the largest chromosomes. Most human cells have 46 molecules of DNA totaling 2 m in length. This makes the average DNA molecule about 43 mm (almost 2 in.) long. To put this in perspective, imagine that an average DNA molecule was scaled up to the diameter of a utility pole (about 20 cm, or 8 in.). At this diameter, a pole proportionate to DNA would rise about 4,400 km (2,700 mi.) into space—far higher than the orbits of the International Space Station (408 km) and the Hubble Space Telescope (600 km).

At the molecular level, DNA and other nucleic acids are polymers of **nucleotides**. A nucleotide consists of a sugar, a phosphate group, and a single- or double-ringed **nitrogenous base** (fig. 4.1a). Two of the bases in DNA—**cytosine (C)** and **thymine (T)**—have a single carbon–nitrogen ring and are classified as *pyrimidines* (py-RIM-ih-deens). The other two bases—**adenine (A)** and **guanine (G)**—have double rings and are classified as *purines* (fig. 4.1b).

The structure of DNA, commonly described as a *double helix*, resembles a spiral staircase (fig. 4.2). Each sidepiece is a backbone composed of phosphate groups alternating with the sugar *deoxyribose*. The steplike connections between the backbones are pairs of nitrogenous bases. The bases face the inside of the helix and hold the two backbones together with hydrogen bonds. Across from a purine on one backbone, there is a pyrimidine on the other. The pairing of each small, single-ringed pyrimidine with a large, double-ringed purine gives the DNA molecule its uniform 2 nm width.

A given purine cannot arbitrarily bind to just any pyrimidine. Adenine and thymine form two hydrogen bonds with each other, and guanine and cytosine form three, as shown in figure 4.2c. Therefore, where there is an A on one backbone, there is normally a T across from it, and every C is normally paired with a G. A—T and C—G are called the **base pairs**. The fact that one strand governs the base sequence of the other is called the **law of complementary base pairing**. It enables us to predict the base sequence of one strand if we know the sequence of the complementary strand.

FIGURE 4.1 Nucleotides and Nitrogenous Bases. (a) The structure of a nucleotide, one of the monomers of DNA and RNA. In RNA, the sugar is ribose. (b) The five nitrogenous bases found in DNA and RNA.

? How would the uniform 2 nm diameter of DNA be affected if two purines or two pyrimidines could pair with each other?

DEEPER INSIGHT 4.1

MEDICAL HISTORY

Discovery of the Double Helix

Credit for determining the double-helical structure of DNA has gone mainly to James Watson and Francis Crick (**fig. 4.3**). The events surrounding their discovery form one of the most dramatic stories of modern science—the subject of many books and at least one movie. When Watson and Crick came to share a laboratory at Cambridge University in 1951, both had barely begun their careers. Watson, age 23, had just completed his Ph.D. in the United States, and Crick, 11 years older, was a doctoral candidate in England. Yet the two were about to become the most famous molecular biologists of the twentieth century, and the discovery that won them such acclaim came without a single laboratory experiment of their own.

Others were fervently at work on DNA, including Rosalind Franklin and Maurice Wilkins at King's College in London. Using a technique called X-ray diffraction, Franklin had determined that DNA had a repetitious helical structure with sugar and phosphate on the outside of the helix. Without her permission, Wilkins showed one of Franklin's best X-ray photographs to Watson. Watson said, "The instant I saw the picture my mouth fell open and my pulse began to race." It provided a flash of insight that allowed the Watson and Crick team to beat Franklin to the goal. Combining what they already knew with the molecular geometry revealed by Franklin's photo, they were quickly able to piece together a scale model that fully accounted for the known geometry of DNA. They rushed a paper into print in 1953 describing the double helix, barely mentioning the importance of Franklin's 2 years of painstaking X-ray diffraction work in unlocking the mystery of life's most important molecule. Franklin published her findings in a separate paper back to back with theirs.

For this discovery and the ensuing decade of research on DNA that it opened up, Watson, Crick, and Wilkins shared the Nobel Prize for Physiology or Medicine in 1962. Nobel Prizes are awarded only to the living, and in the ironic finale of her career, Rosalind Franklin had died in 1958, at the age of 37, of a cancer possibly induced by the X-rays that were her window on DNA architecture.

▶▶▶ APPLY WHAT YOU KNOW

What would be the base sequence of the DNA strand across from ATTGACTCG? If a DNA molecule was known to be 20% adenine, predict its percentage of cytosine and explain your answer.

The essential function of DNA is to carry instructions, called *genes*, for the synthesis of proteins. At this point in the chapter, we will provisionally regard a gene as a segment of DNA that codes for a protein. Later, we shall have to confront the fact that this is an inadequate definition, and we'll examine the meaning of the word more deeply.

Humans are estimated to have about 22,300 genes. These constitute only about 2% of the DNA. The other 98% doesn't code for proteins, but plays various roles in chromosome structure and regulation of gene activity.

4.1b Chromatin and Chromosomes

DNA doesn't exist as a naked double helix in the nucleus of a cell, but is complexed with proteins to form a fine filamentous material called **chromatin**. In most cells, the chromatin occurs as 46 long filaments called **chromosomes**. There is a stupendous amount of DNA in one nucleus—about 2 m (6 ft) of it in the first half of

a cell's life cycle and twice as much when a cell has replicated its DNA in preparation for cell division. It is a prodigious feat to pack this much DNA into a nucleus only about 5 μm in diameter—and in such an orderly fashion that it doesn't become tangled, broken, and damaged beyond use.

In order to achieve such packing, DNA is extensively coiled and supercoiled. **Figure 4.4** shows the successive levels of this organization. The DNA first winds around spools of proteins called *histones* to form the little granules (*core particles*) visible in figure 4.4a. The chromatin then folds into successive zigzags, loops, and coils, getting thicker and shorter as it does so (fig. 4.4b). Ultimately the DNA, itself 2 nm in diameter, is consolidated into chromatin strands 150 times thicker and 1,000 times shorter than the naked DNA. Finally, each chromosome is packed into its own spheroidal region of the nucleus, called a *chromosome territory*. A chromosome territory is permeated with channels that allow regulatory chemicals to have access to the genes.

This is the state of the DNA in a nondividing cell. It's not a static structure, but changes from moment to moment according to the genetic activity of the cell as individual genes are turned on and off. Whole chromosomes migrate to new territories as a cell develops—for example, moving from the edge to the core of a nucleus as its genes are activated for a certain developmental task, or back to the nuclear lamina to silence some genes. This allows genes on different chromosomes to partner with each other in bringing about developmental changes in the cell.

When a cell is preparing to divide, it makes an exact copy of all its nuclear DNA by a process described later, increasing its allotment to about 4 m of DNA. Each chromosome then consists of two parallel filaments called **sister chromatids**. In the early stage of cell division (*prophase*), these chromatids coil some more until each one becomes, at its most compact, 10,000 times shorter but 350 times thicker than the DNA double helix. Only now are the chromosomes thick enough to be seen with a light microscope. This compaction not only allows the 4 m of DNA to

fit in the nucleus, but also enables the two sister chromatids to be pulled apart and carried to separate daughter cells.

Despite all this intricate packaging, the DNA of the average mammalian cell is damaged an astonishing 10,000 to 100,000 times per day! The consequences would be catastrophic were it not for DNA repair enzymes that detect and undo most of the damage.

Figure 4.5 shows the structure of a chromosome in early cell division, when it is compacted to its maximum extent. It consists of two genetically identical, rodlike sister chromatids joined together at a pinched spot called the **centromere**. On each side of the centromere, there is a protein plaque called a **kinetochore**¹ (kih-NEE-to-core), which plays a role in cell division.

4.1c RNA Structure and Function

The nucleotide polymers called **ribonucleic acids (RNAs)** are smaller cousins of DNA. There are many forms of RNA with diverse functions in a cell, but we'll focus on the three that are directly involved in producing proteins: *messenger RNA (mRNA)*, *ribosomal RNA (rRNA)*, and *transfer RNA (tRNA)*. DNA cannot produce proteins without their help. Other RNA types called *non-coding RNA (ncRNA)* play various regulatory and enzymatic roles.

What do mRNA, rRNA, and tRNA have in common, and how do they differ from DNA? The most significant difference is that RNA is much smaller, ranging from about 70 to 90 bases in tRNA to slightly over 10,000 bases in the largest mRNA. DNA, by contrast, averages more than 100 million base pairs long (**table 4.1**). Also, whereas DNA is a double helix, RNA consists of only

TABLE 4.1 Comparison of DNA and RNA		
Feature	DNA	RNA
Sugar	Deoxyribose	Ribose
Types of nitrogenous bases	A, T, C, G	A, U, C, G
Number of nitrogenous bases	Averages 10^8 base pairs	70–10,000 bases, mostly unpaired
Number of nucleotide chains	Two (double helix)	One
Site of action	Functions in nucleus; cannot leave	Leaves nucleus; functions mainly in cytoplasm
Function	Codes for synthesis of RNA and protein	Carries out the instructions in DNA; assembles proteins

one nucleotide chain, not held together by complementary base pairs except in certain regions where the molecule folds back on itself. The sugar in RNA is ribose instead of deoxyribose. RNA contains three of the same nitrogenous bases as DNA—adenine, cytosine, and guanine—but it has no thymine; a base called **uracil (U)** takes its place (see fig. 4.1b).

The essential function of the three principal RNAs is to interpret the code in DNA and use those instructions to synthesize proteins. RNA is a disposable molecule that works mainly in the cytoplasm, while DNA is irreplaceable and remains safely behind in the nucleus, “giving orders” from there. This process is described in the next section of the chapter.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. What are the three components of a nucleotide? Which component varies from one nucleotide to another in DNA?
2. What governs the pattern of base pairing in DNA?
3. What is the difference between DNA and chromatin?
4. Summarize the structural and functional differences between DNA and RNA.

4.2 Genes and Their Action

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. give a working definition of the *gene* and explain why new discoveries in genetics have changed our concept of what a gene is;
- b. explain what the human genome is and what relationship it has to the health sciences;

¹kineto = motion; chore = place

- c. define *genetic code* and describe how DNA codes for protein structure;
- d. describe the process of assembling amino acids to form a protein;
- e. explain what happens to a protein after its amino acid sequence has been synthesized;
- f. describe some ways that a gene can be turned on or off; and
- g. explain how DNA indirectly regulates the synthesis of nonprotein molecules.

4.2a What Is a Gene?

As much as biologists talk about genes, the term is devilishly difficult to define. The word *gene* was coined in 1909 to denote an abstract “unit of heredity” by which a trait passes from parent to offspring. No one had the foggiest idea at the time, though, of what chemical or physical form a gene had—of what a gene *was*. Following discovery of the double helix, molecular biologists worked out the *genetic code* contained in the four bases of DNA and considered a gene to be a segment of the DNA that carries the code for a particular protein. Now, however, we know that the human body has millions of different proteins but only 22,300 protein-coding genes; obviously there isn’t a separate gene for every protein. In addition, we know now that several human genes produce only ncRNA molecules that never go on to direct the synthesis of a protein; RNA is their final product. Other recent discoveries have complicated our concept of the gene still more—genes overlapping each other, so some segments of DNA belong to two different genes; short genes embedded within longer ones; multiple related proteins encoded by a single gene; and other unexpected

arrangements. As molecular biologists have learned more and more about DNA, the definition of the gene has become more and more frayed around the edges.

For the purposes of this introductory book, however, we can settle for an approximate meaning. We will define *gene* as an information-containing segment of DNA that codes for the production of a molecule of RNA, which in most cases goes on to play a role in the synthesis of one or more proteins. The amino acid sequence of a protein is determined by a nucleotide sequence in the DNA.

The 46 human chromosomes come in two sets of 23, one set from each parent. Some of these are gene-rich, such as chromosomes 17, 19, and 22, whereas others are gene-poor, such as 4, 8, 13, 18, 21, and the Y chromosome (see fig. 4.16). All the DNA, both coding and noncoding, in one 23-chromosome set is called the **genome**. The total genome consists of about 3.1 billion nucleotide pairs. Individual genes average about 3,000 nucleotides long, but range up to 2.4 million. Most genes are identical in every human being. All humans, worldwide, are at least 99.99% genetically identical, but even the 0.01% variation means that we can differ from one another in more than 3 million base pairs. Various combinations of these **single-nucleotide polymorphisms**² account for all human genetic variation.

Genomics is a relatively young science concerned with the comprehensive study of the genome and how its genes and noncoding DNA affect the structure and function of the organism. Among the other fruits of this research, we now know the chromosomal locations of more than 1,400 disease-producing mutations. This information has opened the door to a branch of medical diagnosis and therapy called **genomic medicine** (see Deeper Insight 4.2).

²poly = multiple; morph = form

DEEPER INSIGHT 4.2

CLINICAL APPLICATION

Genomic Medicine

Genomic medicine is the application of our knowledge of the genome to the prediction, diagnosis, and treatment of disease. It is relevant to disorders as diverse as cancer, Alzheimer disease, schizophrenia, obesity, and even a person’s susceptibility to nonhereditary diseases such as AIDS and tuberculosis.

Genomic technology has advanced to the point that for less than \$1,000, one can have one’s entire genome scanned for markers of disease risk. Why would anyone want to? Because knowing one’s genome could dramatically change clinical care. It may allow clinicians to forecast a person’s risk of disease and to predict its course; mutations in a single gene can affect the severity of such diseases as hemophilia, muscular dystrophy, cancer, and cystic fibrosis. Genomics should also allow for earlier detection of diseases and for earlier, more effective clinical intervention. Drugs that are safe for most people can have serious side effects in others, owing to genetic variations in drug metabolism. Genomics has begun providing a basis for choosing the safest or most effective drugs and for adjusting dosages for different patients on the basis of their genetic makeup.

Knowing the sites of disease-producing mutations expands the potential for **gene-substitution therapy**. This is a procedure in which cells are removed from a patient with a genetic disorder, supplied with a normal gene in place of the defective one, and reintroduced to the body. The hope is that these genetically modified cells will proliferate and provide patients with gene products they were lacking—perhaps insulin for a patient with diabetes or a blood-clotting factor for a patient with hemophilia. Researchers are currently exploring a new gene-editing technology called *CRISPR-Cas9* that enables one to locate a specific gene in the DNA and remove or replace it. Clinical applicability and safety were still under investigation and in early clinical trials as this textbook edition was written.

Genomics is introducing new problems in medical ethics and law. Should your genome be a private matter between you and your physician? Should an insurance company be entitled to know your genome before issuing health or life insurance to you so it can know your risk of contracting a catastrophic illness, adjust the cost of your coverage, or even deny coverage? Should a prospective employer have the right to know your genome before offering employment? These are areas in which biology, politics, and law converge to shape public policy.

4.2b The Genetic Code

It seems remarkable that the body can make millions of different proteins (called the **proteome**), all from the same 20 amino acids and all encoded by genes made of just 4 nucleotides (A, T, C, G). In the early years after the structure of DNA was discovered, an eminent scientist dismissed it as “a stupid molecule,” too simple and repetitious in its sequence of just four bases, repeated over and over, to be the carrier of so much hereditary information. Some thought heredity must be transmitted by the highly variable proteins of the nucleus, and DNA was just a boring, monotonous scaffold to support them. But DNA, we now appreciate, is a striking illustration of how a great variety of complex structures can be made from a small variety of simpler components. The **genetic code** is a system that enables these 4 nucleotides to code for the amino acid sequences of all proteins.

It’s not unusual for simple codes to represent complex information. Computers store and transmit complex information, including pictures and sounds, in a binary code with only the symbols 1 and 0. Thus, it shouldn’t be surprising that a mere 20 amino acids can be represented by a code of 4 nucleotides; all this requires is to combine these symbols in various ways. It requires more than 2 nucleotides to code for each amino acid, because the A, U, C, and G of mRNA can combine in only 16 different pairs (AA, AU, AC, AG, UA, UU, and so on). The minimum code to symbolize 20 amino acids is 3 nucleotides per amino acid, and indeed, this is the case in DNA. A sequence of 3 DNA nucleotides that stands for 1 amino acid is called a **base triplet**. When messenger RNA is produced, it carries a coded message based on these DNA triplets. A 3-base sequence in mRNA is called a **codon**. The genetic code is expressed in terms of codons.

Table 4.2 shows a few illuminating examples of how the DNA triplets relate to the mRNA codons and how those, in turn, relate to the amino acids of a protein (see appendix D for the entire genetic code). You can see from the table that sometimes two or more codons represent the same amino acid. The reason for this is easy to explain mathematically. Four symbols (N) taken three at a time

(x) can be combined in N^x different ways; that is, there are $4^3 = 64$ possible codons available to represent the 20 amino acids.

Only 61 of these, however, code for amino acids. The other 3—UAG, UGA, and UAA—are called **stop codons**; they signal “end of message,” like the period at the end of a sentence. A stop codon enables the cell’s protein-synthesizing machinery to sense that it has reached the end of the instruction for a particular protein. The codon AUG plays two roles: It serves as a code for methionine and as a **start codon**. This dual function is explained shortly.

4.2c Protein Synthesis

We can now move on to an understanding of how DNA and RNA collaborate to produce proteins. Before studying the details, however, it will be helpful to consider the big picture. In brief, the genetic code in DNA specifies which proteins a cell can make. All the body’s cells except the sex cells and some immune cells contain more or less the same genes. However, different genes are activated in different cells; for example, genes for digestive enzymes are active in stomach cells but not in muscle cells. Any given cell uses only one-third to two-thirds of its genes; the rest remain dormant in that cell, but may be functional in other types of cells.

When a gene is activated, a **messenger RNA (mRNA)** is made—a mirror image of the gene, more or less. Most mRNA migrates from the nucleus to the cytoplasm, where it serves as a code for assembling amino acids in the right order to make a particular protein. In summary, you can think of the process of protein synthesis as DNA $\rightarrow$ mRNA $\rightarrow$ protein, with each arrow reading as “codes for the production of.” The step from DNA to mRNA is called **transcription**, and the step from mRNA to protein is called **translation**. Transcription occurs in the nucleus, where the DNA is. Most translation occurs in the cytoplasm, but 10% to 15% of proteins may be synthesized in the nucleus, with both steps occurring there.

Transcription

DNA is too large to leave the nucleus and participate directly in cytoplasmic protein synthesis. It is necessary, therefore, to make a small mRNA copy that can migrate through a nuclear pore into the cytoplasm. Just as we might transcribe (copy) a document, **transcription** in genetics means the process of copying genetic instructions from DNA to RNA. An enzyme called **RNA polymerase** (po-LIM-ur-ase) binds to the DNA and assembles the RNA. It opens up the DNA helix about 17 base pairs at a time, reading the bases from one strand of the DNA and making a corresponding RNA. Where it finds a C on the DNA, it adds G to the RNA; where it finds an A, it adds U; and so forth. The enzyme then rewinds the DNA helix behind it. Another RNA polymerase may follow closely behind the first one; thus, a gene may be transcribed by several polymerase molecules at once, and numerous copies of the same RNA are made. At the end of the gene is a base sequence that serves as a terminator, which signals the polymerase to stop.

The RNA produced by transcription is an “immature” form called **pre-mRNA**. This molecule contains segments called **exons** that will be translated into a protein, and segments called **introns** that are removed before translation (**fig. 4.6**). Enzymes cut out the introns and splice the exons together into a functional mRNA

TABLE 4.2 Examples of the Genetic Code*

Base Triplet of DNA	Codon of mRNA	Name of Amino Acid	Abbreviation for Amino Acid
CCT	GGA	Glycine	Gly
CCA	GGU	Glycine	Gly
CCC	GGG	Glycine	Gly
CGA	GCU	Alanine	Ala
CGT	GCA	Alanine	Ala
TGG	ACC	Threonine	Thr
TGC	ACG	Threonine	Thr
GTA	CAU	Histidine	His
TAC	AUG	Methionine	Met

*For the complete genetic code, see appendix D.

FIGURE 4.6 Alternative Splicing of mRNA. By splicing together different combinations of exons from a single pre-mRNA, a cell can generate multiple proteins from a single gene.

molecule, which then usually leaves the nucleus. It may help you in remembering these if you think of *introns* being removed while still *in* the nucleus and the *exons* being *exported* from the nucleus to undergo translation in the cytoplasm. The introns aren't entirely useless, but code for a variety of regulatory ncRNAs.

Through a mechanism called *alternative splicing*, one gene can code for more than one protein. Suppose a gene produced a pre-mRNA containing six exons separated by noncoding introns. As shown in figure 4.6, these exons can be spliced together in various combinations to yield codes for two or more proteins. This is a partial explanation of how the body can produce millions of different proteins with little more than 22,000 genes.

Translation

Just as we might translate a work from Spanish into English, genetic **translation** converts the language of nucleotides into the language of amino acids. This job is carried out by the following participants:

1. **Messenger RNA (mRNA)**, which carries the genetic code from the nucleus to the cytoplasm. During its synthesis in the nucleus, mRNA acquires a protein cap that acts like a passport, permitting it to pass through a nuclear pore into the cytosol. The cap also acts as a recognition site that tells a ribosome where to begin translation.
2. **Transfer RNA (tRNA)**, a relatively small RNA whose job is to bind a free amino acid in the cytosol and deliver it to the ribosome to be added to a growing protein chain. tRNA is a single-stranded molecule that turns back and coils on itself to form an angular L shape (**fig. 4.7**). One

FIGURE 4.7 Transfer RNA (tRNA).

loop of the molecule includes an **anticodon**, a series of three nucleotides complementary to a specific codon of mRNA. For the codon AUG, for example, the anticodon is UAC. The other end of the tRNA has an amino acid–accepting end that binds a specific amino acid corresponding to that codon. The first tRNA to bind to a ribosome at the start of translation is called the *initiator tRNA*. It always has the anticodon UAC and always carries the amino acid methionine.

3. **Ribosomes**, the little “reading machines” found in the cytosol and on the outside of the rough ER and nuclear envelope. Inactive ribosomes occur in the cytosol in two pieces—a **small subunit** and a **large subunit**. Each is composed of several enzymes and ribosomal RNA (rRNA) molecules. The two subunits come together only when translating mRNA. A ribosome has three pockets that serve as binding sites for tRNA. In the course of translation, a tRNA usually binds first to the *A site* on one side of the ribosome, then shifts to the *P site* in the middle, and finally to the *E site* on the other side. To remember the order of these sites, it may help you to think of *A* for the site that *accepts* a new amino acid; *P* for the site that carries the growing *protein*; and *E* for *exit*. (*A* and *P* actually stand for *aminoacyl* and *peptidyl* sites.)

Translation occurs in three steps called *initiation*, *elongation*, and *termination*. These are shown in **figure 4.8**, panels 1 through 3; panel 4 illustrates a further aspect of the production of proteins destined to be packaged into lysosomes or secretory vesicles.

- 1 **Initiation.** mRNA passes through a nuclear pore into the cytosol and forms a loop. A small ribosomal subunit binds to a *leader sequence* of bases on the mRNA near the cap, then slides along the mRNA until it recognizes the start codon AUG. An initiator tRNA with the anticodon UAC pairs with the start codon and settles into the P (middle) site of the ribosome with its cargo of methionine (Met). The large subunit of the ribosome then joins the complex. The assembled ribosome now embraces the mRNA in a groove between the subunits and begins sliding along it, reading its bases.
- 2 **Elongation.** The next tRNA arrives, carrying another amino acid; it binds to the A site of the ribosome and its anticodon pairs with the second codon of the mRNA—GCU, for example. A tRNA with the anticodon CGA would bind here, and according to the genetic code, it would carry alanine (Ala). An enzyme in the ribosome transfers the Met of the initiator tRNA to the Ala delivered by the second tRNA and creates a peptide bond between them, giving us a dipeptide, Met—Ala. The ribosome then slides down to read the next codon. This shifts the initiator tRNA (now carrying no amino acid) into the E site, where it leaves the ribosome. The second tRNA (now carrying Met—Ala) shifts into the P site. The now-vacant A site binds a third tRNA. Suppose the next codon is CAU. A tRNA with anticodon GUA would bind here, and would carry histidine

(His). (This is the state shown in the figure.) The ribosome transfers the Met—Ala to the His, creates another peptide bond, and we now have a tripeptide, Met—Ala—His. By repetition of this process, a larger and larger protein is produced. As the protein elongates, it folds into its three-dimensional shape.

Each time a tRNA leaves the E site, it goes off to pick up another amino acid from a pool of free amino acids in the cytosol. One ATP molecule is used in binding the amino acid to the tRNA; therefore, protein synthesis consumes one ATP for every amino acid added to the chain.

All new proteins, as we can see, begin with the amino acid methionine, carried by the initiator tRNA. This is often cleaved off in later processing, however, so not every finished protein starts with methionine.

Codon–anticodon pairing is less precise than just depicted; it tolerates some mismatches, especially at the third base of the codon. Therefore, UGC isn’t necessarily the only anticodon that can pair with ACG. Due to this imprecision or “wobble” in the system, as few as 48 different tRNAs are needed to pair up with the 61 codons that represent the amino acids.

- 3 **Termination.** When the ribosome reaches a stop codon, its A site binds a protein called a *release factor* instead of a tRNA. The release factor causes the finished protein to break away from the ribosome. The ribosome then dissociates into its two subunits, but since these are now so close to the mRNA’s leader sequence, they often reassemble on the same mRNA and repeat the process, making another copy of the same protein.
- 4 **Making proteins for packaging or export.** If a protein is to be packaged into a lysosome or secreted from the cell (such as a digestive enzyme), the ribosome docks on the rough endoplasmic reticulum and the new protein spools off into the cistern of the ER instead of into the cytosol. The ER modifies this protein and packages it into *transport vesicles* whose destiny we will examine later.

One ribosome can work very rapidly, adding about two to six amino acids per second. Most proteins take from 20 seconds to several minutes to make. But a ribosome doesn’t work at the task alone. After one ribosome moves away from the leader sequence, another one often binds there and begins the process, following along behind the first—and then another and another, so that a single mRNA is commonly translated by 10 or 20 ribosomes at once. This cluster of ribosomes, all translating the same mRNA, is called a **polyribosome** (see the photo on the opening page of this chapter). The farther along the mRNA each ribosome is, the longer is the protein spooling from it. Not only is each mRNA translated by all these ribosomes at once, but a cell may have 300,000 identical mRNA molecules, each being simultaneously translated by some 20 ribosomes. With so many “factory workers” doing the same task, a cell may produce over 100,000 protein molecules per second—a remarkably productive factory! As much as 25% of the dry weight of liver cells, which are highly active in protein synthesis, consists of ribosomes.

FIGURE 4.8 Translation of mRNA. Panel 1 depicts mRNA emerging from the nucleus; panels 2 through 4 depict events in the cytoplasm only. See the text for further details of the processes occurring at each step.

? Why would translation not work if ribosomes could bind only one tRNA at a time?

FIGURE 4.9 Relationship of a DNA Base Sequence to Peptide Structure.

Figure 4.9 summarizes transcription and translation and shows how a nucleotide sequence translates to a hypothetical peptide of 6 amino acids. An average protein is about 400 amino acids long; it would have to be represented, at a minimum, by a sequence of 1,203 nucleotides (3 for each amino acid, plus a stop codon).

4.2d Protein Processing and Secretion

Protein synthesis isn't finished when its amino acid sequence (primary structure) has been assembled. To be functional, it must coil or fold into precise secondary and tertiary structures; in some cases, it associates with other protein chains (quaternary structure) or binds with a nonprotein such as a vitamin or carbohydrate. As a new protein is assembled by a ribosome, it is often bound by an older protein called a **chaperone**. The chaperone guides the new protein in folding into the proper shape and helps to prevent improper associations between different proteins. As in the colloquial sense of the word, a chaperone is an older protein that escorts and regulates the behavior of the "youngsters." Some chaperones are also called *stress proteins* or *heat shock proteins* because they're produced in response to heat or other stress on a cell and help damaged proteins fold back into their correct functional shapes.

If a protein is going to be used in the cytosol (for example, the enzymes of glycolysis), it is likely to be made by free ribosomes in the cytosol. However, if it is going to be packaged into a lysosome or secreted from the cell (for example, insulin), the entire polyribosome migrates to the rough ER and docks on its surface. Assembly of the amino acid chain is then completed on the rough ER, and the protein is sent to the Golgi complex for final modification. Thus, we turn to the functions of the ER and Golgi complex in the processing and secretion of a protein. Compare the following description to **figure 4.10**.

① As a protein is assembled on the ER surface, it threads itself through a pore in the ER membrane and into the cistern. Enzymes in the cistern modify the new protein in a variety of ways—removing some amino acid segments, folding the protein and stabilizing it with disulfide bridges, adding carbohydrates, and so forth. Such changes are called **posttranslational modification**. Insulin, for example, is first synthesized as a protein 86 amino acids long. In posttranslational modification, the chain folds back on itself, 3 disulfide bridges are formed, and 35 amino acids are removed from the middle of the protein. The final insulin molecule is therefore made of 2 chains of 21 and 30 amino acids held together by disulfide bridges (see **fig. 2.25**).

② When the rough ER is finished with a protein, it pinches off bubblelike **transport vesicles** coated with a protein called *clathrin*. Clathrin apparently helps to select the proteins to be transported in the vesicles, and as a basketlike cage, it helps to mold the forming vesicles. Soon after the vesicles detach from the ER, they fuse into irregularly shaped clusters that carry their cargo to the Golgi complex.

- ③ As they reach the complex, these clusters fuse and form a new Golgi cistern, called the *cis*³ cistern because it is the one closest to the ER.
- ④ This new cistern migrates through the complex toward the opposite (*trans*) face. It matures as it travels, producing new enzymes that modify the cargo in different ways. For example, it may add carbohydrate chains to the proteins, producing the *glycoproteins* mentioned in chapter 2. Thyroid-stimulating hormone is one such glycoprotein made in this way.
- ⑤ Finally, the *trans*⁴ cistern—the one farthest away from the ER—breaks up into Golgi vesicles laden with the cell product.
- ⑥ Some of the Golgi vesicles become lysosomes, while others become **secretory vesicles** that migrate to the plasma membrane and fuse with it, releasing the cell product by exocytosis. This is how a cell of a salivary gland, for example, secretes mucus and digestive enzymes, and how a cell of the pituitary gland releases thyroid-stimulating hormone.

Table 4.3 summarizes the diverse destinations and functions of newly synthesized proteins.

4.2e Gene Regulation

Genes don't simply produce their products at a steady, incessant pace, like a 24-hour nonstop manufacturing plant. They are

³*cis* = on the same side

⁴*trans* = across from

FIGURE 4.10 Protein Processing and Secretion. See the text for further explanation of the numbered steps.

turned on and off from day to day, even hour to hour, as their products are needed or not, and many genes are permanently turned off in any given cell. The genes for hemoglobin and digestive enzymes, for example, are present but inactive in liver cells and skin cells.

There are several ways to turn genes on or off. We can't consider all of them here, but an example can convey the general principle. Consider a woman who has just given birth to her first baby. In the ensuing days, the hormone *prolactin* stimulates cells of her mammary glands to synthesize the various components of breast milk, including the protein *casein*—something her body has never synthesized before. How is the gene for casein turned on at this point in her life? **Figure 4.11** shows the steps leading from prolactin stimulation to casein secretion.

TABLE 4.3

Some Destinations and Functions of Newly Synthesized Proteins

Destination or Function	Proteins (Examples)
Deposited as a structural protein within cells	Actin of cytoskeleton; keratin of epidermis
Used in the cytosol as a metabolic enzyme	ATPase; kinases
Returned to the nucleus for use in nuclear metabolism	Histones of chromatin; RNA polymerase
Packaged in lysosomes for autophagy, intracellular digestion, and other functions	Numerous lysosomal enzymes
Delivered to other organelles for intracellular use	Catalase of peroxisomes; mitochondrial enzymes
Delivered to plasma membrane to serve transport and other functions	Hormone receptors; sodium–potassium pumps
Secreted by exocytosis for extracellular functions	Digestive enzymes; casein of breast milk

- ① Prolactin binds to its receptor, a pair of proteins in the plasma membrane of the mammary gland cell.
- ② The receptor triggers the activation of a **regulatory protein (transcription activator)** in the cytoplasm.
- ③ The regulatory protein moves into the nucleus and binds to the DNA near the casein gene.
- ④ This binding enables RNA polymerase to bind to the gene and transcribe it, producing the mRNA for casein.
- ⑤ The casein mRNA moves into the cytoplasm and is translated by ribosomes on the rough endoplasmic reticulum.
- ⑥ The Golgi complex packages casein into secretory vesicles.
- ⑦ The secretory vesicles release the casein by exocytosis, and it becomes part of the milk.

At step 4, there are multiple ways that regulatory proteins can activate gene transcription. Some of them attract and position RNA polymerase so it can begin transcribing the gene.

FIGURE 4.11 A Mechanism of Gene Activation. The hormone prolactin triggers intracellular reactions that activate a regulatory protein and lead ultimately to the secretion of casein. See the text for further explanation of the numbered steps.

Others modify the coiling of DNA in a nucleosome in a way that makes specific genes more accessible to RNA polymerase. To turn off a gene, a regulatory protein or ncRNA can coil the chromatin in a different way that makes the gene less accessible, thus preventing transcription. Moving the chromatin over to the nuclear lamina is another way of silencing some of its genes. There are several additional ways, beyond the scope of this book, for inducing or halting the production of a gene product, but the casein example shows how a certain gene may lie dormant in a person until, only a few times in one's life (and only if one bears children), it is activated by a stimulus such as a hormonal signal. Section 4.4h describes a further aspect of gene regulation called *epigenetics*.

4.2f Synthesizing Compounds Other Than Proteins

Cells, of course, make more than proteins—they also synthesize glycogen, fat, steroids, phospholipids, pigments, and many other compounds. There are no genes for these cell products, yet their synthesis is under indirect genetic control. How? They are produced by enzymatic reactions, and enzymes are proteins encoded by genes.

Consider the production of testosterone, for example (**fig. 4.12**). This is a steroid; there is no gene for testosterone. But to make it, a cell of the testis takes in cholesterol and enzymatically converts it to testosterone. This can occur only if the genes for the enzymes are active. Yet a further implication of this is that genes may greatly affect such complex outcomes as behavior, since testosterone strongly influences such behaviors as aggression and sex drive. In short, DNA codes only for RNA and protein synthesis, yet it indirectly controls the synthesis of a much wider range of substances concerned with all aspects of anatomy, physiology, and behavior.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

5. Define *gene*, *genetic code*, *codon*, and *anticodon*.
6. Describe the roles of RNA polymerase, ribosomes, and tRNA in producing a protein.
7. What is the difference between genetic transcription and translation?
8. Summarize the processing of a protein from the time a ribosome finishes its work to the time a protein is secreted from the cell. What roles do the endoplasmic reticulum and Golgi complex play in this?
9. Describe some ways a gene can be turned on or off at different times in a person's life.
10. Considering that genes can code only for RNA or proteins, how can the synthesis of nonprotein substances such as carbohydrates or steroids be under genetic control?

FIGURE 4.12 Indirect Control of Testosterone Synthesis by DNA. There is no gene for testosterone, but DNA regulates its production by coding for enzymes that convert cholesterol to testosterone.

4.3 DNA Replication and the Cell Cycle

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe how DNA is replicated;
- discuss the consequences of replication errors;
- describe the life history of a cell, including the events of mitosis; and
- explain how the timing of cell division is regulated.

Before a cell divides, it must duplicate its DNA so it can give complete and identical copies of all of its genes to each daughter cell. Since DNA controls all cellular function, this replication process must be very exact. We now examine how it is accomplished and consider the consequences of mistakes.

4.3a DNA Replication

The law of complementary base pairing shows that we can predict the base sequence of one DNA strand if we know the sequence

of the other. More importantly, it enables a cell to reproduce one strand based on information in the other. The fundamental steps of the replication process are as follows (**fig. 4.13**):

1. The double helix unwinds from the histones.
2. Like a zipper, an enzyme called **DNA helicase** opens up one short segment of the helix at a time, exposing its nitrogenous bases. The point where the DNA is opened up, like the two halves of a zipper separating, is called the **replication fork**.
3. Molecules of the enzyme **DNA polymerase** move along each strand, read the exposed bases, and like a matchmaker, arrange “marriages” with complementary free nucleotides. If the polymerase finds the sequence TCG, for example, it assembles AGC across from it. The two separated strands of DNA are copied by separate polymerase molecules, proceeding in opposite directions. On one strand (top of figure 4.13), the polymerase moves toward the replication fork and makes a long, continuous, new strand of DNA to complement the old one. On the other strand (bottom of the figure), another polymerase moves away from the replication fork and copies only a short segment of DNA at a time. The segments are then joined together by another enzyme called **DNA ligase**. Ultimately, from the old *parental* DNA molecule, two new *daughter* DNA molecules are made. Each daughter DNA

FIGURE 4.13 Semiconservative DNA Replication. (a) At the replication fork, DNA helicase unwinds the double helix and exposes the bases. DNA polymerases begin assembling new bases across from the existing ones. (b) On one strand, DNA polymerase moves toward the replication fork and makes one long, continuous new DNA strand. (c) On the other strand, DNA polymerases begin at the fork and move away from it, replicating the DNA in short segments with gaps between them. (d) DNA ligase closes the gaps to join the segments into a continuous double helix. (e) The ultimate result is two DNA double helices, each composed of one strand of the original DNA and one newly synthesized strand.

consists of one new helix synthesized from free nucleotides and one old helix conserved from the parental DNA. The process is therefore called **semiconservative replication**.

- While DNA is synthesized in the nucleus, new histones are synthesized in the cytoplasm. Millions of histones are transported into the nucleus within a few minutes after DNA replication, and each new DNA helix wraps around them to make new nucleosomes.

Despite the complexity of this process, each DNA polymerase works at an impressive rate of about 100 base pairs per second. Even at this rate, however, it would take weeks for one polymerase molecule to replicate even one chromosome. But in reality, thousands of polymerase molecules work simultaneously on each DNA molecule, and all 46 chromosomes are replicated in a mere 6 to 8 hours.

4.3b Errors and Mutations

DNA polymerase is fast and accurate, but it makes mistakes. For example, it might read A and place a C across from it where it should have placed a T. If nothing were done to correct such errors, each generation of cells could have thousands of faulty proteins, coded for by DNA that had been miscopied. To prevent such catastrophic damage to the cell, there are multiple modes of correcting replication errors, collectively called the **DNA damage response (DDR)**. DNA polymerase itself double-checks the new base pair and tends to replace incorrect, biochemically unstable pairs with more stable, correct pairs—for example,

removing C and replacing it with T. As a result, only one mistake remains for every billion base pairs replicated—a very high degree of replication accuracy, if not completely flawless.

Changes in DNA structure, called **mutations**,⁵ can result from replication errors or from environmental factors such as radiation, chemicals, and viruses. Uncorrected mutations can be passed on to the descendants of that cell, but many of them have no adverse effect. One reason is that a new base sequence sometimes codes for the same thing as the old one. For example, TGG and TGC both code for threonine (see table 4.2), so a mutation from G to C in the third place wouldn't necessarily change protein structure. Another reason is that a change in protein structure isn't always critical to its function. For example, the beta chain of hemoglobin is 146 amino acids long in both humans and horses, but 25 of these amino acids differ between the two species. Nevertheless, the hemoglobin is fully functional in both species. Furthermore, since 98% of the DNA doesn't code for any proteins, the great majority of mutations don't affect protein structure at all. Other mutations, however, may kill a cell, turn it cancerous, or cause genetic defects in future generations. When a mutation changes the sixth amino acid of β -hemoglobin from glutamic acid to valine, for example, the result is a crippling disorder called sickle-cell disease. Clearly some amino acid substitutions are more critical than others, and this affects the severity of a mutation. More than 30 diseases are known to result from defects in the DNA damage response, including some forms of anemia, cancer, immune deficiency, and brain defects.

⁵muta = change; ation = process

FIGURE 4.14 The Cell Cycle.

4.3c The Cell Cycle

Most cells periodically divide into two daughter cells, so a cell has a life cycle extending from one division to the next. This **cell cycle** is divided into four main phases: G_1 , S , G_2 , and M (fig. 4.14).

G_1 is the **first gap phase**, an interval between cell division and DNA replication. During this time, a cell synthesizes proteins, grows, and carries out its preordained tasks for the body. Almost all of the discussion in this book relates to what cells do in the G_1 phase. Cells in G_1 also accumulate the materials needed to replicate their DNA in the next phase. In cultured cells called fibroblasts, which divide every 18 to 24 hours, G_1 lasts 8 to 10 hours.

S is the **synthesis phase**, in which a cell makes a duplicate copy of its centrioles and nuclear DNA. This is the point at which the cell carries out the semiconservative replication described earlier. The two identical sets of DNA molecules are then available to be divided up between daughter cells at the next cell division. This phase takes 6 to 8 hours in cultured fibroblasts.

G_2 , the **second gap phase**, is the interval (4–6 hours in fibroblasts) between DNA replication and cell division. In G_2 , a cell exhibits further growth, makes more organelles, finishes replicating its centrioles, and synthesizes enzymes that control cell division. It also checks the fidelity of DNA replication and usually repairs any errors that are detected.

M is the **mitotic phase**, in which a cell replicates its nucleus and then pinches in two to form new daughter cells. In cultured fibroblasts, the M phase takes 1 to 2 hours. The details of this phase are considered in the next section. Phases G_1 , S , and G_2 are collectively called **interphase**—the time between M phases.

The length of the cell cycle varies greatly from one cell type to another. Stomach and skin cells divide rapidly, whereas bone and cartilage cells divide slowly. Some cells leave the cell cycle for a “rest” and cease to divide for days, years, or the rest of one’s life—mature neurons, skeletal muscle cells, and adipocytes, for example. Such cells are said to be in the G_0 (**G-zero**) **phase**. The balance between cells that are actively cycling and those standing by in G_0 is an important factor in determining the number of cells in the body. An inability to stop cycling and enter G_0 is characteristic of cancer cells (see Deeper Insight 4.3).

▶▶▶ APPLY WHAT YOU KNOW

What is the maximum number of DNA molecules ever contained in a cell over the course of its life cycle? (Assume the cell has only one nucleus, and disregard mitochondrial DNA.)

4.3d Mitosis

Cells divide by two mechanisms called mitosis and meiosis. Meiosis, however, is restricted to one purpose, the production of eggs and sperm, and is therefore treated in chapter 27 on reproduction. **Mitosis** serves all the other functions of cell division:

- development of an individual, composed of some 50 trillion cells, from a one-celled fertilized egg;
- growth of all tissues and organs after birth;
- replacement of cells that die; and
- repair of damaged tissues.

Four phases of mitosis are recognizable: *prophase*, *metaphase*, *anaphase*, and *telophase* (fig. 4.15).

- 1 **Prophase.**⁶ At the outset of mitosis, the chromosomes shorten and thicken, eventually coiling into compact rods that are easier to distribute to daughter cells than the long, delicate chromatin of interphase. There are 46 chromosomes, each with two chromatids and one molecule of DNA per chromatid. The nuclear envelope disintegrates during prophase and releases the chromosomes into the cytosol. The centrioles begin to sprout elongated microtubules called **spindle fibers**, which push the centrioles apart as they grow. Eventually, a pair of centrioles comes to lie at each pole of the cell. Some spindle fibers grow toward the chromosomes and become attached to the kinetochore on each side of the centromere (see fig. 4.5). The spindle fibers then tug the chromosomes back and forth until they line up along the midline of the cell.

⁶*pro* = first

FIGURE 4.15 Mitosis. The photographs show mitosis in whitefish eggs, where chromosomes are relatively easy to observe. The drawings show a hypothetical cell with only two chromosome pairs; in humans, there are 23 pairs.

1–4: Ed Reschke

- 2 **Metaphase.**⁷ The chromosomes are aligned on the cell equator, oscillating slightly and awaiting a signal that stimulates each of them to split in two at the centromere. The spindle fibers now form a lemon-shaped array called the **mitotic spindle**. Long microtubules reach out from each centriole to the chromosomes, and shorter microtubules form a star-like *aster*,⁸ which anchors the assembly to the inside of the plasma membrane at each end of the cell.
- 3 **Anaphase.**⁹ This phase begins with activation of an enzyme that cleaves the two sister chromatids from each other at the centromere. Each chromatid is now regarded as a separate, single-stranded *daughter chromosome*. One daughter chromosome migrates to each pole of the cell, with its centromere leading the way and the arms trailing behind. Migration is achieved by means of motor proteins in the kinetochore crawling along the spindle fiber as the fiber itself is “chewed up” and disassembled at the chromosomal end.
- 4 **Telophase.**¹⁰ The daughter chromosomes cluster on each side of the cell. The rough ER produces a new nuclear envelope around each cluster, and the chromosomes begin to uncoil and return to the thinly dispersed chromatin form. The mitotic spindle breaks up and vanishes. Each new nucleus forms nucleoli, indicating it has already begun making RNA and is preparing for protein synthesis.

Telophase is the end of nuclear division but overlaps with **cytokinesis**¹¹ (SY-toe-kih-NEE-sis), division of the cytoplasm into two cells. Early traces of cytokinesis are visible even at anaphase. It is achieved by the motor protein myosin pulling on microfilaments of actin in the terminal web of the cytoskeleton. This creates a crease called the *cleavage furrow* around the equator of the cell, and the cell eventually pinches in two. Interphase has now begun for these new cells. Be aware, however, that mitosis (nuclear division) can occur without cytokinesis (cellular division). This is why some cells acquire two or more nuclei or multiple identical sets of chromosomes.

One might think that since DNA is faithfully replicated by complementary base pairing in the S phase, and then the two copies are distributed to the two daughter cells at each mitotic anaphase, the two daughter cells would be genetically identical. One might reasonably expect that all cells of the body, with the exception of the sex cells, are genetically identical. But they're not. We saw earlier that DNA replication isn't error-free, and even after replication, new mutations can arise spontaneously in either strand independently of the other. For this and several other reasons, our somatic (non-sex) cells are genetically variable. One's body is a patchwork of genetic variation—a state known as **genetic mosaicism**. This variation is especially great among our immune cells, sex cells, and neurons. Even so-called identical twins, which arise from a single fertilized egg, aren't really genetically identical. They're born with as many as 100 to 200 gene differences, arising

by new, spontaneous mutations acquired independently of each other while still in the womb.

4.3e Regulation of Cell Division

One of the most important questions in biology is what signals cells when to divide and when to stop. The activation and inhibition of cell division are subjects of intense research for obvious reasons such as management of cancer and tissue repair. Cells divide when (1) they grow large enough to have enough cytoplasm to distribute to their two daughter cells; (2) they have replicated their DNA, so they can give each daughter cell a duplicate set of genes; (3) they receive an adequate supply of nutrients; (4) they are stimulated by **growth factors**, chemical signals secreted by blood platelets, kidney cells, and other sources; or (5) neighboring cells die, opening up space in a tissue to be occupied by new cells. Growth factors and their receptors are a central issue in understanding the uncontrolled growth of cancer (see Deeper Insight 4.3). Cells stop dividing when they snugly contact neighboring cells or when nutrients or growth factors are withdrawn. The cessation of cell division in response to contact with other cells is called **contact inhibition**. An absence of contact inhibition, leading to uncontrolled cell division, is one of the characteristics of cancer.

The cell cycle is regulated by a molecular timer and certain checkpoints at which the cell checks its own status before moving on to the next phase. Two key elements of the timer are families of proteins called **cyclins** and **cyclin-dependent kinases (Cdks)**. A kinase is an enzyme that adds phosphate to other proteins, thereby activating or suppressing their function. Cdks exist at fairly stable levels in cells, but without cyclins, they lie dormant and perform no function. Cyclin levels rise and fall through the cell cycle. In early interphase, cyclin genes are transcribed and cyclin levels rise. As they bind to Cdks, those enzymes phosphorylate proteins with various effects described shortly. At the end of mitosis, proteasomes degrade the cyclins, their levels fall, and the Cdks become dormant again until the next cycle.

At specific **checkpoints** during the cell cycle, a cyclin binds to a Cdk and activates a cascade of biochemical reactions that prepare a cell to move on to the next phase of the cycle. One of these, called the *Start* or *G₁ checkpoint*, either allows the cell to proceed toward the S phase or, if it doesn't, the cell goes into the noncycling *G₀* phase. A *G₂/M checkpoint* late in the *G₂* phase determines whether the cell is able to proceed to mitosis. A third checkpoint at the transition from metaphase to anaphase determines whether the cell can proceed to anaphase, leading to separation of its sister chromatids.

Malfunctions of this process can be disastrous to the cell and even to the life of the whole person. If it fails to allow a cell to progress through the cell cycle, the result can be a failure of tissue maintenance and repair. On the other hand, if the cell cycle progresses too readily, out of control, the result can be uncontrolled tissue growth (neoplasia) and cancer.

Among other functions of cyclin–Cdk complexes, they control (1) the replication of DNA and centrioles in the S phase; (2) the condensation of chromosomes, breakdown of the nuclear envelope, formation of the mitotic spindle, and attachment of chromosomes to the spindle in prophase; and (3) splitting of the centromere and separation of the sister chromatids at anaphase.

⁷meta = next in a series

⁸aster = star

¹⁰telo = end, final

¹¹cyto = cell; kinesis = action, motion

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

11. Describe the genetic roles of DNA helicase and DNA polymerase. Contrast the function of DNA polymerase with that of RNA polymerase.
12. Explain why DNA replication is called *semiconservative*.
13. Define *mutation*. Explain why some mutations are harmless and others can be lethal.
14. List the stages of the cell cycle and summarize what occurs in each one.
15. List the stages of mitosis and the main processes that occur in each one.
16. Concisely explain how cyclins, Cdks, and checkpoints control the cell cycle.

4.4 Chromosomes and Heredity

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the paired arrangement of chromosomes in the human karyotype;
- b. define *allele* and discuss how alleles affect the traits of an individual; and
- c. discuss the interaction of heredity and environment in producing individual traits.

Heredity is the transmission of genetic characteristics from parent to offspring. In the following discussion, we will examine a few basic principles of normal heredity, thus establishing a basis for understanding hereditary traits in later chapters. Hereditary defects are described in chapter 29 along with nonhereditary birth defects.

4.4a The Karyotype

As we have seen, the agents of heredity are the genes, and the genes are carried on the chromosomes. When we lay the 46 chromosomes out in order by size and other physical features, we get a chart called a **karyotype**¹² (fig. 4.16). The chromosomes occur in 23 pairs; the two members of each pair are called **homologous**¹³ **chromosomes** (ho-MOLL-uh-gus). One member of each pair is inherited from the individual's mother and one from the father. Except for the X and Y chromosomes, two homologous chromosomes look alike and carry the same genes, although they may have different varieties of those genes. Chromosomes X and Y are called the **sex chromosomes** because they determine the individual's sex; all the others are called **autosomes**. A female normally has a homologous pair of X chromosomes, whereas a male has one X and a much smaller Y.

FIGURE 4.16 The Normal Human Karyotype. This is a micrograph of chromosomes stained to accentuate their banding patterns. The two chromosomes of each homologous pair exhibit similar size, shape, and banding. Each chromosome at this stage has two chromatids.

▶▶▶ APPLY WHAT YOU KNOW

Why would a cell in metaphase be more useful than a cell in interphase for producing a karyotype?

Any cell with 23 pairs of chromosomes is said to be **diploid**¹⁴ (**2n**). Sperm and egg cells, however, are **haploid**¹⁵ (**n**), meaning they contain only 23 unpaired chromosomes. Sperm and eggs, and cells on their way to becoming sperm and eggs, are called **germ cells (sex cells)**. All other cells of the body are called **somatic cells**. In meiosis (see section 27.4a), the two homologous chromosomes of each pair become *segregated* into separate daughter cells leading to the haploid germ cells. At fertilization, one set of *paternal* (sperm) chromosomes unites with a set of *maternal* (egg) chromosomes, restoring the diploid number to the fertilized egg and the somatic cells that arise from it.

4.4b Genes and Alleles

The positions of specific genes on our 23 paired chromosomes have been well mapped since the massive international Human Genome Project of 1990 to 2003. A gene's position is called its **locus**. Two homologous chromosomes have the same gene at the same locus, but they can carry different forms of that gene, called **alleles**¹⁶ (ah-LEELS), which produce alternative forms of a particular trait.

¹²karyo = nucleus

¹³homo = same; log = relation

¹⁴diplo = double

¹⁵haplo = half

¹⁶allo = different

Typically, one allele is **dominant** and the other one **recessive**. If at least one chromosome carries the dominant allele, a person usually exhibits (“expresses”) the corresponding trait. Even if a recessive allele is present on the other chromosome, its effect is masked by the dominant one. If a dominant allele codes for a particular protein, a recessive allele typically codes for a variant, nonfunctional version of that protein; recessive alleles are sometimes referred to as loss-of-function genes. Their effects are expressed only if present on both chromosomes of the pair. A specific example of this, sickle-cell disease, will be described shortly.

Individuals with identical alleles of a gene on both homologous chromosomes are said to be **homozygous**¹⁷ (HO-mo-ZY-gus) for that gene. If the homologous chromosomes have different alleles for that gene, the individual is **heterozygous**¹⁸ (HET-er-oh-ZY-gus). The paired alleles that an individual possesses for a particular trait constitute the **genotype** (JEE-no-type). An observable trait resulting from that genotype is called the **phenotype**¹⁹ (FEE-no-type). We say that an allele is **expressed** if it shows in the phenotype of an individual so it can be detected by anything from simple observation (such as eye color) to biochemical analysis (such as the presence of a certain enzyme).

Dominant alleles are customarily represented by an italic capital letter such as *A*. The letter is arbitrary but typically stands for the trait under consideration. Recessive alleles are represented by the same letter in lowercase italic, such as *a*. A genotype is usually represented by two letters, such as *AA* for a homozygous dominant pair of alleles, *aa* for homozygous recessive, and *Aa* for heterozygous.

It’s relatively rare for a trait to be determined by only one gene, but such cases are not insignificant. About 25 million Americans have diseases attributed to a single allele: cystic fibrosis, Huntington disease, muscular dystrophy, and sickle-cell disease, among others. **Sickle-cell disease** afflicts about 1.3% of Americans of African ancestry; another 8% are heterozygous **carriers** who don’t have the disease, but carry the recessive allele and may pass it to their children. The carriers are said to have **sickle-cell trait (SCT)**. Sickle-cell disease stems from a recessive allele for one of the proteins that constitute the hemoglobin molecule. In people with sickle-cell disease, hemoglobin turns to a gel at low oxygen levels, as when it passes through the veins. This causes the red blood cells (RBCs) to be distorted into elongated shapes with pointed ends (**fig. 4.17a**). They’re also sticky and clump together, plugging small vessels and causing intense pain, disability, and stunted physical and mental development. Without medical care, a child with sickle-cell disease has little chance of living beyond 2 years. More on the pathology and evolution of sickle-cell disease can be found in chapter 18 (section 18.2e). Here, we will focus on its inheritance.

To examine that, let us represent the dominant allele for normal hemoglobin *H* and the recessive allele for sickle-cell hemoglobin *h*. Homozygous dominant (*HH*) individuals don’t have sickle-cell disease or trait; they can’t pass it to their children. Heterozygous (*Hh*) individuals have the trait but not the disease; they

FIGURE 4.17 Sickle-Cell Disease. (a) Sickled and normal red blood cells (RBCs). (b) Inheritance of sickle-cell disease when both parents are heterozygous carriers. With respect to the two hemoglobin alleles, the four panels of this Punnett square show the possible eggs at the top and possible sperm at the left. Whether a child of this couple has sickle-cell disease or trait depends on which sperm fertilizes which egg. A child of this couple has a 25% chance of normal hemoglobin and not being a carrier for the trait (top left cell); a 50% chance of not having sickle-cell disease but being a carrier for it (top right and bottom left); and a 25% chance of having sickle-cell disease (bottom right).

have the potential to pass it to their children. Homozygous recessive (*hh*) individuals have sickle-cell disease.

A diagram called a **Punnett square** (**fig. 4.17b**) shows the pattern of inheritance of this gene and shows why sickle-cell disease can skip a generation. If a woman is heterozygous, 50% of her eggs will carry allele *H* and 50% will carry allele *h*, as shown across the top of the Punnett square. Similarly, if a man is heterozygous, 50% of his sperm will carry each allele, as shown down

¹⁷*homo* = same; *zygo* = union, joined

¹⁸*hetero* = different; *zygo* = union, joined

¹⁹*pheno* = showing, evident

the left side. If two heterozygous individuals have children, it's a matter of chance which sperm fertilize which eggs, but the four cells within the Punnett square illustrate the possible outcomes. If an H -bearing sperm fertilizes an H -bearing egg, the result is an HH child with normal hemoglobin (upper left cell of the chart). There is a one-in-four (25%) chance of any one of their children having this fortunate outcome. If an h -bearing sperm fertilizes an h -bearing egg, the result is an hh child with sickle-cell disease (lower right cell of the chart). There is also a one-in-four (25%) chance of any one of their children having this tragic outcome. But if an H -bearing sperm fertilizes an h -bearing egg, or an h -bearing sperm fertilizes an H -bearing egg, the result is a heterozygous (Hh) child with normal hemoglobin, but who has sickle-cell trait and could pass it to the next generation. There is a two-in-four (50%) chance of this outcome.

We can infer from this how a recessive trait can skip a generation. Either parent in this chart could have had a parent with sickle-cell disease; he or she would be disease-free (both being heterozygous); but these parents can have a child with sickle-cell. The disease “skipped” this generation of parents, lying hidden in a heterozygous state, but could appear in their parents as well as their children.

For some hereditary diseases, tests are available to detect carriers and allow couples to weigh their risk of having children with genetic disorders. *Genetic counselors* perform genetic testing or refer clients for tests, advise couples on the probability of transmitting genetic diseases, and assist people in coping with genetic diseases.

Would it be possible for a woman with sickle-cell disease to have biological children without it? Use a Punnett square and one or more hypothetical genotypes for the father to demonstrate your point.

4.4c Multiple Alleles, Codominance, and Incomplete Dominance

Some genes exist in more than two allelic forms—that is, there are **multiple alleles** within the collective genetic makeup, or **gene pool**, of the population as a whole. For example, there are over 100 alleles responsible for cystic fibrosis, and there are 3 alleles for ABO blood types. Two of the ABO blood type alleles are dominant and symbolized with a capital I (for *immunoglobulin*) and a superscript: I^A and I^B . There is one recessive allele, symbolized with a lowercase i . Which two alleles one inherits determine the blood type, as follows:

Genotype	Phenotype
$I^A I^A$	Type A
$I^A i$	Type A
$I^B I^B$	Type B
$I^B i$	Type B
$I^A I^B$	Type AB
ii	Type O

▶▶▶ APPLY WHAT YOU KNOW

Why can't one person have all three of the ABO alleles?

Some alleles are equally dominant, or **codominant**. When both of them are present, both are phenotypically expressed. For example, a person who inherits allele I^A from one parent and I^B from the other has blood type AB. These alleles code for enzymes that produce the surface glycolipids of red blood cells. Type AB means that both A and B glycolipids are present, and type O means that neither of them is present.

Other alleles exhibit **incomplete dominance**. When two different alleles are present, the phenotype is intermediate between the traits that each allele would produce alone. Familial hypercholesterolemia, for example, is a disease in which people who inherit an abnormal allele from both parents have blood cholesterol levels up to six times higher than in the general population, whereas those who inherit it from only one parent have levels about two or three times normal. If untreated, those homozygous for the defective allele often die of heart attacks in childhood and untreated heterozygous individuals often die as young adults.

4.4d Polygenic Inheritance and Pleiotropy

Polygenic (multiple-gene) inheritance (fig. 4.18) is a phenomenon in which genes at two or more loci, or even on different chromosomes, contribute to a single phenotypic trait. Human eye, hair, and skin colors are normal polygenic traits, for example. They each result from the combined expression of more than 100 genes, making it impossible to reliably predict traits of

FIGURE 4.18 Polygenic Inheritance of Eye Color. A polygenic trait such as eye color is determined by the contributions of genes at multiple loci. Only 3 hypothetical genes are represented, but eye color is influenced by more than 100.

(top): Dan Kosmayer/Shutterstock; (middle): Igor_khabal/Shutterstock; (bottom): coloroftime/Getty Images

FIGURE 4.19 Pleiotropy in Alkaptonuria. Multiple phenotypic effects can result from a single gene mutation.

the offspring from those of their parents (see chapter 6). Several diseases are also thought to stem from polygenic inheritance, including some forms of alcoholism, mental illness, cancer, and heart disease.

Pleiotropy²⁰ (ply-OT-roe-pee) is a phenomenon in which one gene produces multiple phenotypic effects. For example, about 1 in 200,000 people has a genetic disorder called *alkaptonuria*, caused by a mutation on chromosome 3. The mutation blocks the normal breakdown of the amino acid tyrosine, resulting in the accumulation of an intermediate breakdown product, homogentisic acid, in the body fluids and connective tissues. When homogentisic acid oxidizes, it binds to collagen and turns the tissues gray to bluish black, and for unknown reasons, it causes degeneration of cartilages and other connective tissues. Among the multiple phenotypic effects of this disorder (**fig. 4.19**) are darkening of the skin; darkening and degeneration of the cartilages in places such as the ears, knees, and intervertebral discs; darkening of the urine when it stands long enough for the homogentisic acid to oxidize; discoloration of the teeth and the whites of the eyes; arthritis of the shoulders, hips, and knees; and damage to the heart valves, prostate gland, and other internal organs—numerous effects from just one gene! Another well-known example of pleiotropy is sickle-cell disease, detailed in chapter 18.

²⁰*pleio* = more; *trop* = changes

FIGURE 4.20 Sex-Linked Inheritance of Red–Green Color Blindness. Left: A female who inherits a recessive allele (*c*) for color blindness from one parent but a dominant allele (*C*) for normal vision from her other parent will have normal color vision. Right: A male who inherits *c* from his mother will exhibit red–green color blindness; the Y chromosome from his father has no corresponding gene to mask the effect of *c*.

4.4e Sex Linkage

Sex-linked traits are carried on the X or Y chromosome and therefore tend to be inherited by one sex more than the other. Males are more likely than females to have red–green color blindness or hemophilia, for example, because the allele for each is recessive and located on the X chromosome (*X-linked*). Females have two X chromosomes. If a female inherits the recessive color-blindness allele (*c*) on one X chromosome, there is still a good chance that her other X chromosome will carry a dominant allele (*C*) for normal color vision. Males, on the other hand, have only one X chromosome and normally express any allele found there (**fig. 4.20**). Ironically, even though color blindness is far more common among males, it can be inherited only from their mothers. Why? Because only the mother contributes an X chromosome. If a male child inherits *c* on his mother's X chromosome, he will be color-blind. He has no “second chance” to inherit a normal allele on a second X chromosome. A female would have to inherit it from both parents in order for her to have a trait such as red–green color blindness. That happens, but is relatively rare.

The X chromosome carries about 900 genes, most of which have nothing to do with determining an individual's sex. There are so few functional genes (55) on the Y chromosome—concerned mainly with development of the testes—that all proven sex-linked traits are associated with the X chromosome.

Even though males don't inherit an X chromosome from their fathers, it is possible—indeed not uncommon—for them to inherit some genes from the father's X chromosome. This

happens because, in the male parent, X and Y chromosomes often exchange a few genes in the *pseudoautosomal* regions at their tips. Conversely, in rare cases, a daughter can inherit her father's male-determining *SRY* gene because it has transferred to the X chromosome he passes on to her. Thus, an XY male could inherit a Y chromosome without that “male-determining” gene, and an XX female could inherit an X chromosome with the “male-determining” *SRY* gene. This is one reason why a person's gender isn't always rigidly determined by inheritance of an X versus a Y chromosome.

4.4f Dominant and Recessive Alleles at the Population Level

It is a common misconception that dominant alleles must be more common in the gene pool than recessive alleles. The truth is that dominance and recessiveness have little to do with how common an allele is. For example, type O is the most common ABO blood type in North America, but it is caused by the recessive allele *i*. Blood type AB, caused by the two dominant ABO alleles, is the rarest. *Polydactyly*,²¹ the presence of extra fingers or toes, is a dominant trait, yet rare in the population (1 in every 700 to 1,000 live births).

4.4g Environmental Effects and Gene Expression

It's one thing for any given cell to have all the usual genes in its nucleus, but it's a different matter whether those genes are turned on or off—whether the cell shows any detectable effects from them. For a gene to be turned on and have an effect on the individual is called **gene expression**. Even if an allele is dominant, it isn't always expressed in the phenotype. If a dominant allele is silenced and has no effect on some people who carry it, it is said to show **incomplete penetrance** in that population—that is, the genotype doesn't “penetrate to” and affect everyone who has it.

One reason the connection between genotype and phenotype isn't inevitable is that environmental factors play an important role in the expression of all genes. At the very least, all gene expression depends on nutrition. Brown eyes, for example, require not only genes for the enzymes that synthesize the pigment melanin, but also the dietary raw material, phenylalanine, from which the melanin is made (**fig. 4.21**).

No gene can produce a phenotypic effect without nutritional and other environmental input, and no nutrients can produce a body or specific phenotype without genetic instructions that tell cells what to do with them. Just as you need both a recipe and ingredients to make a cake, it takes both heredity and environment to make a phenotype.

FIGURE 4.21 The Roles of Environment and Heredity in Producing a Phenotype. Brown eye color requires phenylalanine from the diet (environment) and two genetically coded (hereditary) enzymes to convert phenylalanine to melanin, the eye pigment.

eyes: Dan Kosmayer/Shutterstock

4.4h Epigenetics

It is often superficially believed that the only way gene expression can change is for the DNA base sequence to change—that is, through mutation. It is clear, however, that other mechanisms called **epigenetic**²² effects can alter gene expression—reversibly activating or silencing genes without changes in base sequence. Among these are variations in the higher-order packaging of chromatin, modification of the histones, gene silencing by noncoding RNA (ncRNA), and *DNA methylation*—adding methyl ($-\text{CH}_3$) groups to DNA bases, especially cytosine, with usually a gene-silencing effect.

Many epigenetic changes occur normally and affect such things as how stem cells end up as liver, nerve, or skin cells. Different kinds of body cells are almost genetically identical, yet very different in structure and function because of epigenetic effects. Some epigenetic changes, however, may trigger such diseases and disorders as cancer, obesity, diabetes mellitus, or heart disease. Epigenetics is thought to be a possible culprit, for example, in the hereditary disorder *Prader–Willi syndrome*,²³ in which gene silencing leads to diverse effects including poor muscle tone, short stature, overeating, and childhood behavioral problems.

²¹*poly* = many; *dactyl* = fingers, toes

²²*epi* = after, beyond, above the level of; *genet* = the gene or genome

²³Andrea Prader (1919–2001) and Heinrich Willi (1900–1971), Swiss pediatricians

Particularly striking is the fact of **epigenetic inheritance**; we can pass on changes in gene expression to the next generation without changes in the base sequence of the genes themselves. Our habits and experiences today may affect gene expression in our children and perhaps even grandchildren. Anything from diet, smoking, or the use of recreational drugs to pollution, stress, epidemics, or famines can have epigenetic effects lasting for another generation or two. In light of epigenetics, we must now view heredity as entailing not only the genes passed from one generation to the next, but also whether other factors have abnormally activated or silenced those genes.

DEEPER INSIGHT 4.3

CLINICAL APPLICATION

Cancer

Anyone awaiting the results of a tumor biopsy hopes for the good news: **benign**! This means the tumor is slow-growing, contained in a fibrous capsule, and won't metastasize. In most cases, it's relatively easy to treat. The dreaded news is that it's **malignant**, meaning it tends to grow rapidly, it's not encapsulated, and it's prone to metastasize—to give off cells that seed the growth of multiple tumors elsewhere, such as colon cancer metastasizing to the lungs and brain.

Oncology is a medical specialty that deals with both benign and malignant tumors, but only malignancies are called cancer. The word *cancer* literally means “crab.” Hippocrates was the first to use the word this way, upon seeing a breast tumor with a tangle of blood vessels that reminded him of a crab's outstretched legs. Energy-hungry tumors often stimulate such ingrowth of blood vessels—a phenomenon called *tumor angiogenesis*.

Cancers are named for the tissue of origin: *carcinomas* originate in epithelial tissue; *lymphomas* in the lymph nodes; *melanomas* in pigment cells (melanocytes) of the epidermis; *leukemias* in blood-forming tissues such as bone marrow; and *sarcomas* in bone, other connective tissue, or muscle. About 90% of malignancies are carcinomas.

Mutation

Only 5% to 10% of cancers are hereditary, but cancer is always a genetic disease. This is not as contradictory as it may seem. Most cases are due to mutations arising anew in the affected individual, not genes inherited from a parent. Mutations can arise through errors in DNA replication every time cells divide, or from exposure to **carcinogens**—radiation such as ultraviolet rays and X-rays; chemicals such as cigarette tar; and viruses such as human papillomavirus (HPV), hepatitis C, and type 2 herpes simplex.

Oncologists are especially interested in two families of cancer genes called oncogenes and tumor suppressor genes. An **oncogene** is analogous to a stuck accelerator on a car—it causes cell division to accelerate out of control, sometimes by inducing the excessive secretion of growth factors that stimulate mitosis, or the production of excessive growth-factor receptors, making cells oversensitive to even a normal level of growth factor. An oncogene called *ras* underlies about one-quarter of human cancers, and oncogene *erbB2* is a common factor in breast and ovarian cancer. **Tumor suppressor (TS) genes** inhibit cancer by opposing oncogene action, coding for DNA-repair enzymes,

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

17. Why must the carrier of a genetic disease be heterozygous?
18. State at least three reasons why a person's phenotype can't always be determined from the genotype.
19. A male can inherit color blindness only from his mother, whereas a female must inherit it from both her father and mother to show the trait. Explain this apparent paradox.

and other means. Consequently, mutations that destroy their protective “braking” function can lead to cancer. Mutation of a TS gene called *TP53*, for example, is involved in about 50% of cases of leukemia and colon, lung, breast, liver, brain, and esophageal tumors. Many human cancers are associated, however, not with mutation but with aberrant DNA methylation, which can, for example, silence one's TS genes and turn off their protective function.

Cancer seldom results from just one mutation. It usually requires 5 to 10 mutations at different gene loci. It takes time for so many mutations to accumulate, which is why cancer is more common in the elderly than in the young. In addition, as we age, we accrue more lifetime exposure to carcinogens, our DNA- and tissue-repair mechanisms become less efficient, and our immune system grows weaker and less able to detect and destroy malignant cells.

Metastasis

Cancer typically begins with a single cell that has experienced multiple mutations, leading it to divide out of control and grow into a larger and larger mass—the *primary tumor*. The hallmark of cancer is **metastasis**²⁴—the ability of malignant cells to spread from the primary tumor and seed the growth of new tumors elsewhere, detached from the primary one (**fig. 4.22**). Motility and invasion are two key characteristics of metastasizing cells. Depending on the type of cancer, malignant cells can travel in the lymphatic vessels, blood vessels, along nerves, or along the basal surfaces of epithelia, among other routes.

Recent research has shown that just prior to metastasis, primary tumors emit chemical signals (*cytokines*) that stimulate other tissues and organs to prepare for arriving metastatic cells. Those tissues produce a modified cellular–biochemical environment that functions as a more favorable bed for metastatic cells to settle down and grow in. The cancer behaves in some respects like a parasite, adapted to promote its own success, survival, and spread. Unlike true parasites, however, cancer cannot spread from one person to another.

²⁴*meta* = beyond; *stasis* = a stable condition

FIGURE 4.22 Metastasis. The process by which malignant cells escape from a primary tumor, travel in the blood or lymph, and seed the growth of new (metastatic) tumors in other localities. Colon cancer, for example, can metastasize to the liver or brain by this method.

Mortality

About one in five of us in the United States will die of cancer—one of the highest rates in the world—with the five highest tolls taken by lung, colorectal, liver, stomach, and breast cancer, in descending order. If left untreated, cancer is almost always fatal. Why?

- For one reason, malignant tumors replace functional tissue in vital organs. Kidney cancer can destroy most of the blood-filtering units (*nephrons*) of the kidneys, letting toxic wastes build up to lethal levels (**fig. 4.23**). Lung cancer can destroy much of the gas-exchange tissue (*alveoli*) of the lungs, making it increasingly hard to breathe, leading to a low blood oxygen level and multisystem organ failure as oxygen-starved, CO₂-poisoned tissues die.
- Growing tumors can put lethal pressure on vital organs like the brain. They can compress bronchi and prevent adequate ventilation of the lungs, or compress major blood vessels and shut down circulation. Ovarian tumors, for example, can grow to the size of oranges, even grapefruits, and larger. In the crowded pelvic cavity, they can compress the major arteries and veins that serve the lower limbs, causing catastrophic circulatory failure.
- The erosion of blood vessels by tumors can cause them to hemorrhage, with vomiting or coughing up blood and unseen hemorrhaging into the body cavities.
- Cancer weakens the immune system, leaving the body open to attack by *opportunistic infections* that a healthy person could

FIGURE 4.23 Wilms Tumor. A malignant tumor of the kidney occurring especially in children.

From the University of Alabama at Birmingham, Department of Pathology PEIR Digital Library © <http://peir.net>

ward off. Leukemia, for example, produces a great overpopulation of white blood cells (WBCs) (see fig. 18.19). Since WBCs are our disease-fighting cells, one might think this was a good thing. However, the leukemic cells are immature and can't perform that function. A body overrun with leukemia is like a nation with a huge standing army, but composed of 10-year-old children who can't fight effectively to defend it.

- Energy- and nutrient-hungry tumors outcompete healthy tissues, starving the body for energy. As muscle, fat, and other tissues atrophy, cancer victims can waste away to an alarmingly emaciated degree called *cachexia*²⁵ (ka-KEX-ee-ah), lapsing into fatigue, coma, and death from sheer exhaustion.

Treatment

Cancer is usually treated with surgery, chemotherapy, or radiation therapy. In the worst cases, the body can become widely riddled with tumors, all of which started out as a single cell in someplace such as the lung, breast, skin, or colon. At that point, a cure usually can't be achieved by surgery, and one's best hope may lie in something that acts body-wide such as chemotherapy, radiation therapy, or immunotherapy.

It is simplistic and misguided to hope for "a cure for cancer." Cancer isn't one disease and won't have one cure. Many people have already been cured of some cancers, whereas other cancers haven't yet yielded to the skills of oncologists, and new forms of cancer are still evolving. Some lively areas of cancer research today are drugs called *angiogenesis inhibitors* that prevent tumors from growing the dense plexus of blood vessels they need to survive; *cancer immunotherapy*, programming one's own immune cells (T cells) to selectively recognize and attack tumor cells; and *cancer genomics*, tailoring treatment to the unique genetic makeup of each patient.

²⁵ *cach* = bad; *exia* = condition

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

4.1 DNA and RNA—The Nucleic Acids

1. The general name of the monomers that compose DNA and RNA; the three universal structural components of each monomer; the purines and pyrimidines involved in DNA and RNA structure; and how a purine differs from a pyrimidine
2. Structure of the double helix of DNA; what holds the two strands of the helix together; why DNA normally has only A—T and C—G base pairs (not A—C or G—T); and the law of complementary base pairing
3. The approximate number of genes in the human genome; what percentage of the DNA consists of genes; and to what extent, and in what ways, the remaining DNA may serve a purpose
4. How DNA and protein are combined to form chromatin; how the chromatin is coiled and supercoiled to fit into the compact cell nucleus and minimize damage; and the role of histones and nucleosomes in the organization of chromatin
5. The structure of a metaphase chromosome and how many chromosomes are in a typical cell
6. How RNA differs from DNA in structure and function, and the three types of RNA involved in protein synthesis

4.2 Genes and Their Action

1. The definition of *gene*; how genes relate to the amino acid sequence of proteins; why it cannot be said that every gene codes for protein structure; and why not every protein is encoded by its own unique gene
2. Definitions of *genome*, *genomics*, and *genomic medicine*
3. The organization of nucleotides into DNA triplets; how these relate to but differ from the codons of mRNA; the number of codons; and stop codons and their function
4. How the genetic code relates mRNA codons to protein structure
5. The process and outcome of genetic transcription; the enzyme that carries it out; the difference between pre-mRNA and mRNA; and the significance of introns and exons

6. How alternative splicing partially explains why the diversity of human proteins vastly exceeds the number of human genes
7. The process and outcome of genetic translation; the roles of mRNA, tRNA, and ribosomes in translation
8. Posttranslational modification of proteins, where it occurs, and how new proteins destined for extracellular use are packaged and released from a cell
9. How gene expression can be turned on or off according to the functions of different kinds of cells or physiological needs that change over time, such as a temporary need for breast milk
10. How the synthesis of nonproteins such as carbohydrates and steroids is regulated by the genes, even though genes code only for RNA or protein

4.3 DNA Replication and the Cell Cycle

1. Why every generation of cells must synthesize new DNA even though the chromosome number remains constant from generation to generation
2. Semiconservative replication, the enzymes that carry it out, and why it results in two DNA molecules that each contain one old and one new nucleotide polymer
3. What a mutation is and how a cell detects and corrects most mutations that arise during DNA replication; the varied consequences of uncorrected mutations
4. The four stages of the cell cycle, what occurs in each stage, and which stages occur during interphase
5. The functions of mitosis; its four stages; what occurs in each stage; and why the amount of DNA in a cell is halved by mitosis, yet the number of chromosomes remains the same
6. Cytokinesis and how it overlaps but differs from telophase
7. How mitosis can be either stimulated or inhibited according to the need for tissue maintenance or growth
8. How cyclins and cyclin-dependent kinases regulate the cell cycle

4.4 Chromosomes and Heredity

1. The definition of *heredity*
2. Organization of the karyotype; the number of homologous pairs of human

- chromosomes; why chromosomes occur in homologous pairs; and the differences between haploid and diploid cells and between germ cells and somatic cells
3. The differences between autosomes and sex chromosomes, and which sex chromosomes occur in males and females
4. Dominant and recessive alleles, the difference between homozygous and heterozygous individuals, and why a person can be homozygous for some alleles and heterozygous for others
5. The relationship of genotype to phenotype, the difference between the two, and why phenotype is not determined solely by genotype
6. Why a recessive trait can skip a generation, with examples; what is meant by a *carrier*
7. The differences between the genotype, genome, and gene pool; why a genotype can never be composed of more than two alleles of the same gene, but the gene pool can contain three or more alleles of one gene
8. How codominance and incomplete dominance differ from simple dominance of an allele
9. What polygenic inheritance and pleiotropy imply about the relationship between a certain phenotype and its associated genes; examples of both
10. Why some traits occur more in males than in females, the name of this phenomenon, and examples
11. Why some individuals may not exhibit the phenotype that one would predict from their genotype; the name for this incomplete expression of certain genotypes
12. Why it cannot be said that any human trait is exclusively the result of the genes or of the environment; an example that demonstrates this
13. Why it cannot be said that dominant alleles are the most common ones in a population and recessive alleles are less common; examples that support this point
14. The meaning of *gene expression* and the variety of factors that affect it
15. How heredity and health are affected not only by genetic changes (mutations) but also epigenetic ones

Answers in Appendix A

- Production of more than one phenotypic trait by a single gene is called
 - pleiotropy.
 - genetic determinism.
 - codominance.
 - penetrance.
 - genetic recombination.
- When a ribosome reads a codon on mRNA, it must bind to the _____ of a corresponding tRNA.
 - start codon
 - stop codon
 - intron
 - exon
 - anticodon
- The normal functions of a liver cell—synthesizing proteins, detoxifying wastes, storing glycogen, and so forth—are done during its
 - anaphase.
 - telophase.
 - G₁ phase.
 - G₂ phase.
 - synthesis phase.
- Two genetically identical strands of a metaphase chromosome, joined at the centromere, are its
 - kinetochores.
 - centrioles.
 - sister chromatids.
 - homologous chromatids.
 - nucleosomes.
- Which of the following is *not* found in DNA?
 - thymine
 - phosphate
 - cytosine
 - deoxyribose
 - uracil
- Genetic transcription is performed by
 - ribosomes.
 - RNA polymerase.
 - DNA polymerase.
 - helicase.
 - chaperones.
- A chaperone comes into play in
 - the folding of a new protein into its tertiary structure.
 - keeping DNA organized within the nucleus.
 - escorting sister chromatids to opposite daughter cells during mitosis.
 - repairing DNA that has been damaged by mutagens.
 - guiding metastatic cancer cells to their destination.
- An allele that is not phenotypically expressed in the presence of an alternative allele of the same gene is said to be
 - codominant.
 - lacking penetrance.
 - heterozygous.
 - recessive.
 - subordinate.
- Semiconservative replication occurs during
 - transcription.
 - translation.
 - postranslational modification.
 - the S phase of the cell cycle.
 - mitosis.
- Mutagens sometimes cause no harm to cells for all of the following reasons *except*
 - some mutagens are natural, harmless products of the cell itself.
 - most of the human DNA doesn't code for any proteins.
 - the body's DNA repair mechanisms detect and correct genetic damage.
 - change in a codon doesn't always change the amino acid encoded by it.
 - some mutations change protein structure in ways that aren't critical to normal function.
- The cytoplasmic division at the end of mitosis is called _____.
- At the checkpoints of the cell cycle, proteins called cyclins bind to _____ and activate reactions that enable the cell to proceed to the next stage of the cycle.
- The pattern of mRNA nitrogenous bases that represents the 20 amino acids of a protein is called the _____.
- Several ribosomes attached to one mRNA, which they are all transcribing, form a cluster called a/an _____.
- The enzyme that produces pre-mRNA from the instructions in DNA is _____.
- All the DNA in a haploid set of chromosomes is called a person's _____.
- At prophase, a cell has _____ chromosomes, _____ chromatids, and _____ molecules of DNA. (How many of each?)
- The cytoplasmic granule of RNA and protein that reads the message in mRNA is a/an _____.
- Cells are stimulated to divide by chemical signals called _____.
- All chromosomes except the sex chromosomes are called _____.

▶ Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

STUDY GUIDE

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. Proteins destined to be exported from a cell are made by ribosomes on the surface of the Golgi complex.
2. Steroids, carbohydrates, and phospholipids are encoded by different types of genes than are proteins.
3. Since uracil and thymine are very similar, a molecule of RNA would have about the same molecular weight as a stretch of DNA of the same length.
4. Each amino acid of a protein is represented by its own unique base pair in DNA.
5. Each gene codes for just one protein.
6. The law of complementary base pairing describes the way the bases in an mRNA codon pair up with the bases of a tRNA anticodon during translation.
7. All human DNA codes for the synthesis of proteins.
8. All mutations result in the production of defective proteins and are therefore harmful.
9. Males have only one sex chromosome whereas females have two.
10. A gene can be transcribed by only one RNA polymerase at a time.

► Testing Your Comprehension

1. Why would the supercoiled, condensed form of chromosomes seen in metaphase not be suitable for the G_1 phase of the cell cycle? Why would the finely dispersed chromatin of the G_1 phase not be suitable for mitosis?
2. Suppose a woman was heterozygous for blood type A and her mate had blood type AB. With the aid of a Punnett square, explain what blood type(s) their children could possibly have.
3. Given the information in this chapter, present an argument that evolution is not merely possible but inevitable. (*Hint:* Review the definition of *evolution* in chapter 1.)
4. What would be the minimum length (approximate number of bases) of an mRNA that coded for a protein 300 amino acids long?
5. Biology textbooks once taught the concept of “one gene, one protein”—that a gene is a segment of DNA that codes for just one protein, and every protein is represented by a separate, unique gene. Discuss the evidence that shows this can no longer be regarded as true.

Module 3: Tissues

BRUSHING UP

- This chapter details the structure of the body’s serous and mucous membranes; refresh your memory of where such membranes are found in atlas A, section A.3.
- Connective tissues are characterized by a large amount of ground substance, two of the chief components of which are the glycoproteins and proteoglycans introduced in section 2.4c.
- The terminology of cell shapes introduced in figure 3.1 is used in the naming of epithelial tissue in this chapter.
- Secretory vesicles and exocytosis (see section 3.3f) are central to understanding the gland types to be introduced in this chapter.

With its 50 trillion cells and thousands of organs, the human body may seem to be a structure of forbidding complexity. Fortunately for our health, longevity, and self-understanding, biologists of the past weren’t discouraged by this, but discovered patterns that made it more understandable. One such pattern is the fact that these trillions of cells belong to only 200 types or so, and they are organized into tissues that fall into just four primary categories—*epithelial*, *connective*, *nervous*, and *muscular tissue*—although there are at least 23 subtypes of these four.

Organs derive their function not from their cells alone but from how the cells are organized into tissues. Cells are specialized for certain tasks: muscle contraction, defense, enzyme secretion, and so forth. No one cell type can carry out all of the body’s vital functions. Cells therefore work together at certain tasks and form tissues that carry out a particular function, such as nerve signaling or nutrient digestion. An organ is a structure with discrete boundaries that is composed of two or more tissue types.

The study of tissues and how they are arranged into organs is called **histology**,¹ or **microscopic anatomy**—the subject of

this chapter. Here we study the four tissue classes; the variations within each class; how to recognize tissue types microscopically and relate their microscopic anatomy to their function; how tissues are arranged to form an organ; how tissues change as they grow, shrink, or change from one tissue type to another over the life of the individual; and modes of tissue degeneration and death. Histology bridges the gap between the cytology of the preceding chapters and the organ system approach of the chapters that follow.

5.1 The Study of Tissues

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name the four primary classes into which all adult tissues are classified;
- b. name the three embryonic germ layers and some adult tissues derived from each; and
- c. visualize the three-dimensional shape of a structure from a two-dimensional tissue section.

5.1a The Primary Tissue Classes

A **tissue** is a group of similar cells and cell products that arise from the same region of the embryo and work together to perform a specific structural or physiological role in an organ. The four *primary tissues*—epithelial, connective, nervous, and muscular—are summarized in **table 5.1**. They differ in the types and functions of their cells, the characteristics of the **matrix (extracellular material)** that surrounds the cells, and the relative amount of space occupied by the cells and matrix. In muscle and epithelium, the cells are so close together that the matrix is scarcely visible, but in most connective tissues, the matrix occupies much more space than the cells do.

TABLE 5.1 The Four Primary Tissue Classes

Type	Definition	Representative Locations
Epithelial	Tissue composed of layers of closely spaced cells that cover organ surfaces, form glands, and serve for protection, secretion, and absorption	Epidermis Inner lining of digestive tract Liver and other glands
Connective	Tissue with usually more matrix than cell volume, often specialized to support and protect organs and to bind other tissues and organs to each other	Tendons and ligaments Cartilage and bone Blood
Nervous	Tissue containing excitable cells specialized for rapid transmission of coded information to other cells	Brain Spinal cord Nerves
Muscular	Tissue composed of elongated, excitable muscle cells specialized for contraction	Skeletal muscles Heart (cardiac muscle) Walls of viscera (smooth muscle)

Photos (Epithelial, Nervous, Muscular): Ed Reschke/Photolibrary/Stone/Getty Images; (Connective): Dennis Strete/McGraw Hill

¹histo = tissue; logy = study of

The matrix is composed of fibrous proteins and, usually, a clear gel variously known as **ground substance**, **tissue fluid**, **extracellular fluid (ECF)**, or **interstitial² fluid**. The ground substance contains water, gases, minerals, nutrients, wastes, hormones, and other chemicals. This is the medium from which all cells obtain their oxygen, nutrients, and other needs, and into which cells release metabolic wastes, hormones, and other products. In cartilage and bone, the matrix is a rubbery or stony material rather than a gel or fluid.

In summary, a tissue is composed of cells and matrix, and the matrix is composed of fibers and ground substance.

5.1b Embryonic Tissues

Human development begins with a single cell, the fertilized egg, which soon divides to produce scores of identical, smaller cells. The first tissues appear when these cells start to organize themselves into layers—first two, and soon three strata called the **primary germ layers**, which give rise to all of the body's mature tissues. The three primary germ layers are called *ectoderm*, *mesoderm*, and *endoderm*. The **ectoderm³** is an outer layer that gives rise to the epidermis and nervous system. The innermost

layer, the **endoderm⁴**, gives rise to the mucous membranes of the digestive and respiratory tracts and to the digestive glands, among other things. Between these two is the **mesoderm⁵**, a layer of more loosely organized cells. Mesoderm eventually turns to a gelatinous tissue called **mesenchyme**, composed of fine, wispy collagen (protein) fibers and branching *mesenchymal cells* embedded in ground substance. Mesenchyme gives rise to cardiac muscle, bone, and blood, among other tissues. (The development of the three primary tissues in the embryo is detailed at “Embryogenesis” in section 29.1f.) Most organs are composed of tissues derived from two or more primary germ layers. The rest of this chapter concerns the “mature” tissues that exist from infancy through adulthood.

5.1c Interpreting Tissue Sections

In your study of histology, you may be presented with various tissue preparations mounted on microscope slides. Most such preparations are thin slices called **histological sections**. The best anatomical insight depends on an ability to deduce the three-dimensional structure of an organ from these two-dimensional sections (**fig. 5.1**). This ability, in turn, depends on an awareness of how tissues are prepared for study.

²*inter* = between; *stit* = to stand

³*ecto* = outer; *derm* = skin

⁴*endo* = inner; *derm* = skin

⁵*meso* = middle; *derm* = skin

FIGURE 5.1 Three-Dimensional Interpretation of Two-Dimensional Images. (a) A boiled egg. Grazing sections (top left and right) would miss the yolk, just as a tissue section may miss a nucleus or other structure. (b) Elbow macaroni, which resembles many curved ducts and tubules. A section far from the bend would give the impression of two separate tubules; a section near the bend would show two interconnected lumina (cavities); and a section still farther down could miss the lumen completely. (c) A coiled gland in three dimensions and as it would look in a vertical tissue section of a tissue such as the lining of the uterus.

Histologists use a variety of techniques for preserving, sectioning (slicing), and staining tissues to show their structural details as clearly as possible. Tissue specimens are preserved in a **fixative**—a chemical such as formalin that prevents decay. After fixation, most tissues are cut into sections typically only one or two cells thick. Sectioning is necessary to allow the light of a microscope to pass through and so the image is not confused by too many layers of overlapping cells. The sections are then mounted on slides and artificially colored with histological **stains** to enhance detail. If they're not stained, most tissue sections appear a hazy gray. With stains that bind to different components of a tissue, however, you may see pink cytoplasm; violet nuclei; and blue, green, or golden-brown protein fibers, depending on the stain used.

Sectioning a tissue reduces a three-dimensional structure to a series of two-dimensional slices. You must keep this in mind and try to translate the microscopic image into a mental image of the whole structure. Like the boiled egg and elbow macaroni in figure 5.1, an object may look quite different when it is cut at various levels, or *planes of section*. A coiled tube, such as a gland of the uterus (fig. 5.1c), is often broken up into multiple portions since it meanders in and out of the plane of section. An experienced viewer, however, recognizes that the separated pieces are parts of a single tube winding its way to the organ surface. Note that a grazing slice through a boiled egg might miss the yolk, just as a tissue section might miss the nucleus of a cell even though it was present.

Many anatomical structures are longer on one axis than another—the humerus and esophagus, for example. A tissue cut on its long axis is called a **longitudinal section (l.s.)**, and one cut perpendicular to this is a **cross section (c.s.)**. A section cut on a slant between a longitudinal and cross section is an **oblique section**. **Figure 5.2** shows how certain organs look when sectioned on each of these planes.

Not all histological preparations are sections. Liquid tissues such as blood and soft tissues such as spinal cord may be prepared as **smears**, in which the tissue is rubbed or spread across the slide rather than sliced. Some membranes and cobwebby tissues, like the *areolar tissue* in figure 5.14, are sometimes mounted as **spreads**, in which the tissue is laid out on the slide, like placing a small square of tissue paper or a tuft of lint on a sheet of glass.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. Classify each of the following into one of the four primary tissue classes: the skin surface, fat, the spinal cord, most heart tissue, bone, tendons, blood, and the inner lining of the stomach.
2. What are tissues composed of in addition to cells?
3. What embryonic germ layer gives rise to nervous tissue? To the liver? To muscle?
4. What is the term for a thin, stained slice of tissue mounted on a microscope slide?

FIGURE 5.2 Three Planes of Section. A bone and blood vessel are used to relate a two-dimensional sectioned appearance to a three-dimensional structure. (a) Longitudinal sections. (b) Cross sections. (c) Oblique sections.

? Would you classify the egg sections in the previous figure as longitudinal, cross, or oblique sections? How would the egg look if sectioned in the other two planes?

5.2 Epithelial Tissue

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the properties that distinguish epithelium from other tissue classes;
- list and classify eight types of epithelium, distinguish them from each other, and state where each type can be found in the body;
- explain how the structural differences between epithelia relate to their functional differences; and
- visually recognize each epithelial type from specimens or photographs.

Epithelial⁶ tissue consists of a sheet of closely adhering cells, one or more cells thick, with the upper surface usually exposed to the environment or to an internal space in the body. Epithelium covers the body surface (skin), lines body cavities, forms the external and internal linings of many organs, and constitutes most gland tissue. The functions of epithelial tissue include

- **Protection.** Epithelia protect deeper tissues from invasion and injury. The epidermis of the skin, for example, is a barrier to infection, and the inner lining of the stomach protects its deeper tissues from stomach acid and enzymes.
- **Secretion.** Epithelia produce mucus, sweat, enzymes, hormones, and most of the body's other secretions; glands are composed largely of epithelial tissue.
- **Excretion.** Epithelia void wastes from the tissues, such as CO₂ across the pulmonary epithelium and bile from the epithelium of the liver.
- **Absorption.** Epithelia absorb chemicals from the adjacent medium; nutrients, for example, are absorbed through the epithelium of the small intestine.
- **Filtration.** All substances leaving the blood are selectively filtered through the epithelium that lines the blood vessels; all urinary waste is filtered through epithelia of the kidneys.
- **Sensation.** Epithelia are provided with nerve endings that sense stimulation ranging from a touch on the skin to irritation of the stomach.

The cells and extracellular material of an epithelium can be loosely compared to the bricks and mortar of a wall. The extracellular material ("mortar") is so thin, however, that it is barely visible with a light microscope, and the cells appear pressed close together. Epithelia are *avascular*⁷ (without blood vessels)—there is no room for them between the cells. Epithelia, however, usually lie on a vessel-rich layer of connective

tissue, which furnishes them with nutrients and waste removal. Epithelial cells closest to the connective tissue typically exhibit a high rate of mitosis. This allows epithelia to repair themselves quickly—an ability of special importance in protective epithelia that are highly vulnerable to such injuries as skin abrasions and erosion by stomach acid.

Between an epithelium and the underlying connective tissue is a layer called the **basement membrane**. It contains collagen, glycoproteins, and other protein-carbohydrate complexes, and blends into other proteins of the connective tissue. The basement membrane serves to anchor an epithelium to the connective tissue; it controls the exchange of materials between the epithelium and the underlying tissues; and it binds growth factors from below that regulate epithelial development. The surface of an epithelial cell that faces the basement membrane is its **basal surface**, the one that faces away from it toward the body surface or the internal cavity (lumen) of an organ is the **apical surface**, and between these two, the sidewall of a cell is called the **lateral surface**.

Epithelia are classified into two broad categories—*simple* and *stratified*—with four types in each category. In a simple epithelium, every cell is anchored to the basement membrane, whereas in a stratified epithelium, some cells rest on top of other cells and don't contact the basement membrane (fig. 5.3).

Table 5.2 (containing figs. 5.4 to 5.7) summarizes the structural and functional differences between the four simple epithelia. In this and subsequent tables, each photograph is accompanied by a labeled drawing of the same specimen. The drawings clarify cell boundaries and other relevant features that may otherwise be difficult to see or identify in photographs or through the microscope. Each figure indicates the approximate magnification at which the original photograph was made. Each is enlarged much more than this when printed in the book, of course, but selecting the closest magnification on a microscope should enable you to see a comparable level of detail (resolution).

5.2a Simple Epithelia

Generally, a **simple epithelium** has only one layer of cells, although this is a somewhat debatable point in the *pseudostratified columnar* type. Three types of simple epithelia are named for the shapes of their cells: **simple squamous**⁸ (thin scaly cells), **simple cuboidal** (squarish or round cells), and **simple columnar** (tall narrow cells). In the fourth type, **pseudostratified columnar**, not all cells reach the surface; the shorter cells are covered by the taller ones. This epithelium looks stratified in most tissue sections, but careful examination, especially with the electron microscope, shows that every cell reaches the basement membrane—like trees in a forest, where some grow taller than others but all are anchored in the soil below.

Simple columnar and pseudostratified columnar epithelia often have wineglass-shaped **goblet cells** that produce protective

⁶*epi* = upon; *theli* = nipple, female

⁷*a* = without; *vas* = blood vessels

⁸*squam* = scale

FIGURE 5.3 Cell Shapes and Epithelial Types. (a) Frontal sections of three classes of epithelium. Pseudostratified columnar epithelium is a special type of simple epithelium that gives a false appearance of multiple cell layers. (b) Frontal and oblique views of three cell shapes—squamous, cuboidal, and columnar. Note that these traditional terms describe the frontal appearance, but all three are polygonal when viewed from above.

mucous coats over the mucous membranes. These cells have an expanded apical end filled with secretory vesicles; their product becomes mucus when it is secreted and absorbs water. The basal part of the cell is a narrow stem, like that of a wineglass, that reaches to the basement membrane.

5.2b Stratified Epithelia

Stratified epithelia range from 2 to 20 or more layers of cells, with some cells resting directly on others and only the deepest layer attached to the basement membrane (table 5.3, containing figs. 5.8 to 5.11). Three of the stratified epithelia are named for the shapes of their surface cells: **stratified squamous**, **stratified cuboidal**, and **stratified columnar epithelia**. The deeper cells, however, may be of a different shape than the surface cells. The fourth type, **urothelium**, is named for the fact that it's unique to the urinary tract. It is often called by an older name, **transitional epithelium**, that arose from a misunderstanding that it represented a transitional stage between stratified squamous and stratified columnar epithelium.

Stratified columnar epithelium is rare and of relatively minor importance—seen only in places where two other epithelial types meet, as in limited regions of the pharynx, larynx, anal canal, and male urethra. We will not consider this type any further.

The most widespread epithelium in the body is stratified squamous epithelium, which deserves further discussion. Its deepest cells are cuboidal to columnar, and include mitotically active stem cells. Their daughter cells push toward the surface and become flatter (more scaly) as they migrate farther upward, until they finally die and flake off. Their loss is called **exfoliation (desquamation)** (fig. 5.12); the study of exfoliated cells is

called *exfoliate cytology*. You can easily study exfoliated cells by scraping your gums with a toothpick, smearing this material on a slide, and staining it with iodine for microscopic examination. A similar procedure is used in the *Pap smear*, an examination of exfoliated cells from the uterine cervix for signs of cancer (see fig. 28.7).

Stratified squamous epithelia are of two kinds—keratinized and nonkeratinized. A **keratinized (cornified)** epithelium, found in the epidermis, is covered with a layer of dead compressed cells. These cells, called **keratinocytes**, are packed with the durable protein *keratin* and coated with a water-repellent glycolipid. The skin surface is therefore relatively dry; it retards water loss from the body; and it resists penetration by disease organisms. (Keratin is also the protein of which animal horns are made, hence its name.⁹) The tongue, esophagus, vagina, and a few other internal membranes are covered with the **nonkeratinized** type, which lacks the surface layer of dead cells. This type provides a surface that is, again, abrasion-resistant, but also moist and slippery. These characteristics are well suited to resist stress produced by chewing and swallowing food and by sexual intercourse and childbirth.

Urothelium is another particularly interesting type of stratified epithelium. Why is it limited to the urinary tract? The answer relates to the fact that urine is usually acidic and hypertonic to the intracellular fluid. It would tend to draw water out of the cells by osmosis and kill them if there were nothing to protect them.

(text continued after table 5.3)

⁹kerat = horn

TABLE 5.2 Simple Epithelia

Simple Squamous Epithelium

(a)

(b)

FIGURE 5.4 Simple Squamous Epithelium. Alveoli of the lung (×400). (a) Light micrograph. (b) Labeled drawing. **APR**

a: Al Telser/McGraw Hill

Microscopic appearance: Single layer of thin cells, shaped like fried eggs with bulge where nucleus is located; nucleus flattened in the plane of the cell, like an egg yolk; cytoplasm may be so thin it is hard to see in tissue sections; in surface view, cells have angular contours and nuclei appear round

Representative locations: Air sacs (alveoli) of lungs; glomerular capsules of kidneys; some kidney tubules; inner lining (endothelium) of heart and blood vessels; serous membranes of stomach, intestines, and some other viscera; surface mesothelium of pleura, pericardium, peritoneum, and mesenteries

Functions: Allows rapid diffusion or transport of substances through membrane; secretes lubricating serous fluid

Simple Cuboidal Epithelium

(a)

(b)

FIGURE 5.5 Simple Cuboidal Epithelium. Kidney tubules (×400). (a) Light micrograph. (b) Labeled drawing. **APR**

a: Dennis Strete/McGraw Hill

Microscopic appearance: Single layer of square or round cells; in glands, cells often pyramidal and arranged like segments of an orange around a central space; spherical, centrally placed nuclei; with a brush border of microvilli in some kidney tubules; ciliated in bronchioles of lung

Representative locations: Liver, thyroid, mammary, salivary, and other glands; most kidney tubules; bronchioles

Functions: Absorption and secretion; production of protective mucous coat; movement of respiratory mucus

TABLE 5.2 Simple Epithelia (*continued*)

Simple Columnar Epithelium

(a)

(b)

FIGURE 5.6 Simple Columnar Epithelium. Mucosa of the small intestine (×400). (a) Light micrograph. (b) Labeled drawing.

APR

a: Ed Reschke/Photolibrary/Stone/Getty Images

Microscopic appearance: Single layer of tall, narrow cells; oval or sausage-shaped nuclei, vertically oriented, usually in basal half of cell; apical portion of cell often shows secretory vesicles visible with TEM; often shows a brush border of microvilli; ciliated in some organs; may possess goblet cells

Representative locations: Inner lining of stomach, intestines, gallbladder, uterus, and uterine tubes; some kidney tubules

Functions: Absorption; secretion of mucus and other products; movement of egg and embryo in uterine tube

Pseudostratified Columnar Epithelium

(a)

(b)

FIGURE 5.7 Ciliated Pseudostratified Columnar Epithelium. Mucosa of the trachea (×400). (a) Light micrograph. (b) Labeled drawing.

APR

a: Dennis Strete/McGraw Hill

Microscopic appearance: Looks multilayered; some cells do not reach free surface, but all cells reach basement membrane; nuclei at several levels in deeper half of epithelium; often with goblet cells; often ciliated

Representative locations: Respiratory tract from nasal cavity to bronchi; portions of male urethra

Functions: Secretes and propels mucus

TABLE 5.3 Stratified Epithelia

Stratified Squamous Epithelium—Keratinized

(a)

(b)

FIGURE 5.8 Keratinized Stratified Squamous Epithelium.

Epidermis of the sole of the foot (x400). (a) Light micrograph. (b) Labeled drawing. **APR**

a: Ed Reschke

Microscopic appearance: Multiple cell layers with cells becoming increasingly flat and scaly toward surface; surface covered with a layer of compact dead cells without nuclei; basal cells may be cuboidal to columnar

Representative locations: Epidermis; palms and soles are especially heavily keratinized

Functions: Resists abrasion and penetration by pathogenic organisms; retards water loss through skin

Stratified Squamous Epithelium—Nonkeratinized

(a)

(b)

FIGURE 5.9 Nonkeratinized Stratified Squamous Epithelium.

Mucosa of the vagina (x400). (a) Light micrograph. (b) Labeled drawing. **APR**

a: Ed Reschke/Stone/Getty Images

Microscopic appearance: Same as keratinized epithelium but without the surface layer of dead cells

Representative locations: Tongue, oral mucosa, esophagus, anal canal, vagina

Functions: Resists abrasion and penetration by pathogenic organisms

TABLE 5.3 Stratified Epithelia (continued)	
Stratified Cuboidal Epithelium	Urothelium
 (a)  (b)	 (a)  (b)
FIGURE 5.10 Stratified Cuboidal Epithelium. Duct of a sweat gland (x400). (a) Light micrograph. (b) Labeled drawing. APR a: Lester V. Bergman/Corbis NX/Getty Images Microscopic appearance: Two or more layers of cells; surface cells square or round Representative locations: Sweat gland ducts; egg-producing vesicles (follicles) of ovaries; sperm-producing ducts (seminiferous tubules) of testis Functions: Contributes to sweat secretion; secretes ovarian hormones; produces sperm	FIGURE 5.11 Urothelium. Kidney (x400). (a) Light micrograph. (b) Labeled drawing. APR a: Johnny R. Howze/McGraw Hill Microscopic appearance: Somewhat resembles stratified squamous epithelium, but surface cells are rounded, not flattened, and often bulge at surface; typically five or six cells thick when relaxed and two or three cells thick when stretched; cells may be flatter and thinner when urothelium is stretched (as in a distended bladder); some cells have two nuclei Representative locations: Urinary tract—part of kidney, ureter, bladder, part of urethra Functions: Stretches to allow filling of urinary tract; protects underlying tissues from osmotic damage by urine

FIGURE 5.12 Exfoliation of Squamous Cells from the Mucosa of the Vagina.

? Aside from the gums and vagina, name another epithelium in the body that would look like this to the scanning electron microscope.

David M. Phillips/Science Source

The domed surface cells of urothelium, however, have a unique protective property. They are called **umbrella cells**. On the upper surface of an umbrella cell, the outer phospholipid layer of the plasma membrane is thicker than usual and has dense patches called *lipid rafts* with embedded proteins called *uroplakins*. Uroplakins are impermeable to urine and protect the urothelium, including the cytoplasm of the umbrella cell itself. Lipid rafts are connected to each other by hinges of ordinary plasma membrane. When the bladder is empty and relaxed, these plaques fold at the hinges (like folding a laptop computer) and drop into the cell interior for storage, and the cell bulges upward as seen in figure 5.11. As the bladder fills with urine, the hinges open (like opening the computer), the plaques spread out over the surface to protect the cell, and the umbrella cells become thinner and flatter. Not surprisingly, this type of epithelium is best developed in the bladder, where it is subject to prolonged contact with stored urine.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

5. Distinguish between simple and stratified epithelia, and explain why pseudostratified columnar epithelium belongs in the former category despite its superficial appearance.
6. Explain how to distinguish a stratified squamous epithelium from a urothelium.
7. What function do keratinized and nonkeratinized stratified squamous epithelia have in common? What is the structural difference between these two? How is this structural difference related to a functional difference between them?
8. How do the epithelia of the esophagus and stomach differ? How does this relate to their respective functions?

DEEPER INSIGHT 5.1

CLINICAL APPLICATION

Biopsy

Biopsy¹⁰ means the removal and microscopic examination of a sample of living tissue. One purpose of a biopsy is diagnosis of diseases that can be identified only from the microscopic appearance of cells or tissues—for example, a malignancy such as colon cancer, an infection such as tuberculosis, or an inflammatory disease such as lupus. Diagnosis may include the *staging* of a cancer to express how advanced it is. (See Deeper Insight 28.1, Pap Smears and Cervical Cancer.) Another purpose is treatment planning. The appropriate drug for cancer chemotherapy, for example, may depend on the type of cancer revealed by the biopsy, and for cervical or breast cancer, it depends on the stage of the cancer. A third purpose is surgical guidance. A specimen from a patient undergoing lumpectomy for breast cancer, for example, may be examined for *clear margins* so the surgeon can know if all the malignant tissue has been removed or it is necessary to cut more widely.

Cutting out and examining an entire suspicious mass, such as a breast lump or lymph node, is called *excisional biopsy*. An *incisional*

biopsy is removal of just a portion of the mass, such as a suspected skin melanoma, for diagnostic examination. A *needle biopsy* is done to obtain a sample of cells when it isn't necessary to maintain the exact structure of the tissue, such as a sample of bone marrow for the diagnosis of leukemia. Sucking out such a specimen with a needle is called *needle aspiration biopsy*. A *core needle biopsy* employs a wide-bore needle and sometimes an instrument with jaws, inserted through a needle, to take a “bite” of the suspicious tissue or remove an entire mass such as a colon polyp. In some procedures called *CT-guided needle biopsy*, exact placement of the needle is guided by watching it on a CT monitor.

In some cases, the biopsy specimen is examined by an in-house pathologist while the patient is still under anesthesia and the surgeon awaits the lab report in order to know how to proceed. In outpatient cases, a specimen such as a lymph node may be sent to a medical diagnostics laboratory elsewhere, which reports the result back to the physician.

5.3 Connective Tissue

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the properties that most connective tissues have in common;
- discuss the types of cells found in connective tissue;
- explain what the matrix of a connective tissue is and describe its components;
- name and classify 10 types of connective tissue, describe their cellular components and matrix, and explain what distinguishes them from each other; and
- visually recognize each connective tissue type from specimens or photographs.

5.3a Overview

Connective tissues are the most abundant, widely distributed, and histologically variable of the primary tissues. They include fibrous tissue, adipose tissue, cartilage, bone, and blood. Such diverse tissues may seem to have little in common, but as a rule, their cells occupy less space than the extracellular matrix. Usually their cells are not in direct contact with each other, but are separated by expanses of matrix. Connective tissues vary greatly in vascularity, from rich networks of blood vessels in the loose connective tissues to no blood vessels in cartilage.

The functions of connective tissue include

- **Binding of organs.** Tendons bind muscle to bone, ligaments bind one bone to another, fat holds the kidneys and eyes in place, and fibrous tissue binds the skin to underlying muscle.
- **Support.** Bones support the body; cartilage supports the ears, nose, larynx, and trachea; fibrous tissues form the framework of organs such as the spleen.
- **Physical protection.** The cranium, ribs, and sternum protect delicate organs such as the brain, lungs, and heart; fatty cushions protect the kidneys and eyes.
- **Immune protection.** Connective tissue cells attack foreign invaders, and loose connective tissue forms a “battlefield” under the skin and mucous membranes where immune cells can be quickly mobilized against disease agents.
- **Movement.** Bones provide the lever system for body movement, cartilages are involved in movement of the vocal cords, and cartilages on bone surfaces ease joint movements.
- **Storage.** Fat is the body’s major energy reserve; bone is a reservoir of calcium and phosphorus that can be drawn upon when needed.
- **Heat production.** Metabolism of brown fat generates heat in infants and children.
- **Transport.** Blood transports gases, nutrients, wastes, hormones, and blood cells.

The mesenchyme described earlier in this chapter is a form of embryonic connective tissue. The mature connective tissues fall into four broad categories: fibrous connective tissue, adipose tissue, supportive connective tissues (cartilage and bone), and fluid connective tissue (blood).

5.3b Fibrous Connective Tissue

Fibrous connective tissue is the most diverse type. Nearly all connective tissues contain fibers, but the tissues considered here are classified together because the fibers are so conspicuous. Fibers are, of course, just one component of the tissue, which also includes cells and ground substance. Before examining specific types of fibrous connective tissue, let’s examine these components.

Components of Fibrous Connective Tissue

Cells The cells of fibrous connective tissue include the following types:

- **Fibroblasts.**¹¹ These are large, fusiform or stellate cells that often show slender, wispy branches. They produce the fibers and ground substance that form the matrix of the tissue.
- **Macrophages.**¹² These are large phagocytic cells that wander through the connective tissues, where they engulf and destroy bacteria, other foreign particles, and dead or dying cells of our own body. They also activate the immune system when they sense foreign matter called *antigens*. They arise from white blood cells called *monocytes* or from the same stem cells as monocytes.
- **Leukocytes,**¹³ or **white blood cells (WBCs).** WBCs travel briefly in the bloodstream, then crawl out through the walls of small blood vessels and spend most of their time in the connective tissues. The two most common types are *neutrophils*, which wander about attacking bacteria, and *lymphocytes*, which react against bacteria, toxins, and other foreign agents. Lymphocytes often form dense patches in the mucous membranes.
- **Plasma cells.** Certain lymphocytes turn into plasma cells when they detect foreign agents. The plasma cells then synthesize disease-fighting proteins called *antibodies*. Plasma cells are rarely seen except in lymph nodes, the wall of the intestines, and inflamed tissue.
- **Mast cells.** These cells, found especially alongside blood vessels, secrete a chemical called *heparin* that inhibits blood clotting, and one called *histamine* that increases blood flow by dilating blood vessels.
- **Adipocytes** (AD-ih-po-sites), or **fat cells.** These appear in small clusters in some fibrous connective tissues. When they dominate an area, the tissue is called *adipose tissue*.

¹¹fibro = fiber; blast = producing

¹²macro = big; phage = eater

¹³leuko = white; cyte = cell

FIGURE 5.13 Tendons and Ligament. The tendons of the hand and the ligamentous band (extensor retinaculum) of the wrist are composed of collagen, which has a white glistening appearance.
Rebecca Gray/McGraw Hill

Fibers Three types of protein fibers are found in fibrous connective tissues:

- **Collagenous fibers** (col-LADJ-eh-nus). These fibers, made of **collagen**, are tough and flexible and resist stretching. Collagen is the body's most abundant protein, constituting about 25% of the total. It is the base of such animal products as gelatin, leather, and glue.¹⁴ In fresh tissue, collagenous fibers have a glistening white appearance, as seen in tendons and some cuts of meat (**fig. 5.13**); thus, they are often called *white fibers*. In tissue sections, collagen forms coarse, wavy bundles, often dyed pink, blue, or green by the most common histological stains. Tendons, ligaments, and the dermis of the skin are made mainly of collagen. Less visibly, collagen pervades the matrix of cartilage, bone, and muscles.
- **Reticular¹⁵ fibers.** These are thin collagen fibers coated with glycoprotein. They form a spongelike framework for

such organs as the spleen and lymph nodes and constitute part of the basement membranes underlying epithelia.

- **Elastic fibers.** These are thinner than collagenous fibers, and they branch and rejoin each other along their course. They are made of a protein called **elastin** coated with a glycoprotein (*fibrillin*). The coiled structure of elastin allows it to stretch and recoil like a rubber band. Elastic fibers account for the ability of the skin, lungs, and arteries to spring back after they are stretched. (Elasticity isn't the ability to stretch, but the tendency to recoil when tension is released.)

Ground Substance Amid the cells and fibers in some tissue sections, there appears to be a lot of empty space. In living tissue, this space is occupied by the featureless **ground substance**. Ground substance usually has a gelatinous to rubbery consistency resulting from three classes of large molecules: glycosaminoglycans, proteoglycans, and adhesive glycoproteins. It absorbs compressive forces and, like the styrofoam packing in a shipping carton, protects the more delicate cells from mechanical injury.

A **glycosaminoglycan (GAG)** (GLY-co-seh-ME-no-GLY-can) is a long polysaccharide composed of unusual disaccharides called *amino sugars* and *uronic acid*. GAGs are negatively charged and thus tend to attract sodium and potassium ions, which in turn cause them to absorb and retain water. Thus, GAGs play an important role in regulating the water and electrolyte balance of tissues. The most common GAG is **chondroitin sulfate** (con-DRO-ih-tin). It is abundant in blood vessels and bones and gives cartilage its relative stiffness. Other GAGs that you will read of elsewhere in this book are *heparin* (an anticoagulant) and *hyaluronic acid* (HY-uh-loo-RON-ic). The latter is a gigantic molecule up to 20 μm long, as large as most cells. It is a viscous, slippery substance that forms a lubricant in the joints and constitutes much of the jellylike *vitreous body* of the eyeball.

A **proteoglycan** is another gigantic molecule. It is shaped somewhat like a bottle brush, with a central core of protein and bristlelike outgrowths composed of GAGs. The entire proteoglycan may be attached to hyaluronic acid, thus forming an enormous molecular complex. Proteoglycans form thick colloids similar to those of gravy, gelatin, and glue. This gel slows the spread of pathogenic organisms through the tissues. Some proteoglycans are embedded in the plasma membranes of cells, attached to the cytoskeleton on the inside and to other extracellular molecules in the matrix. They create a strong structural bond between cells and extracellular macromolecules and help to hold tissues together.

Adhesive glycoproteins are protein-carbohydrate complexes that bind plasma membrane proteins to extracellular collagen and proteoglycans. They bind the components of a tissue together and mark paths that guide migrating embryonic cells to their destinations in a tissue.

Types of Fibrous Connective Tissue

Fibrous connective tissue is divided into two broad categories according to the relative abundance of fiber: *loose* and *dense connective tissue*. In **loose connective tissue**, much of the space is occupied by ground substance, which dissolves out of the tissue during histological fixation and leaves empty space in prepared tissue sections. The loose connective tissues we will discuss

¹⁴*colla* = glue; *gen* = producing

¹⁵*ret* = network; *icul* = little

are *areolar* and *reticular tissue* (table 5.4). In **dense connective tissue**, fiber occupies more space than the cells and ground substance, and appears closely packed in tissue sections. We will discuss two types: *dense regular* and *dense irregular connective tissue* (table 5.5).

Areolar¹⁶ **tissue** (AIR-ee-OH-lur) exhibits loosely organized fibers, abundant blood vessels, and a lot of seemingly empty space. It possesses all six of the aforementioned cell types. Its fibers run in seemingly random directions and are mostly collagenous, but elastic and reticular fibers are also present. Areolar tissue is highly variable in appearance. In many serous membranes, it looks like **figure 5.14**, but in the skin and mucous membranes, it is more compact (see fig. 5.8) and sometimes difficult to distinguish from dense irregular connective tissue. Some advice on how to tell them apart is given after the discussion of dense irregular connective tissue.

Areolar tissue is found in tissue sections from almost every part of the body. It surrounds blood vessels and nerves and penetrates with them even into the small spaces of muscle, tendon, brain, and other tissues. Nearly every epithelium rests on a layer of areolar tissue, whose blood vessels provide the epithelium with nutrition, waste removal, and a ready supply of infection-fighting leukocytes in times of need. Because of the abundance of open, fluid-filled space, leukocytes can move about freely in areolar tissue and easily find and destroy pathogens.

Reticular tissue (fig. 5.15) is a mesh of reticular fibers and fibroblasts. It forms the framework (stroma) of such organs as the lymph nodes, spleen, thymus, and bone marrow. The space amid the fibers is filled with blood cells. If you imagine a sponge soaked with blood, the sponge fibers are analogous to the reticular tissue stroma.

Dense regular connective tissue (fig. 5.16) is named for two properties: (1) The collagen fibers are closely packed (dense) and leave relatively little open space, and (2) the fibers are parallel to each other (regular). It is found especially in tendons and ligaments. The parallel arrangement of fibers is an adaptation to the fact that musculoskeletal stresses pull tendons and ligaments in predictable directions. With minor exceptions such as blood vessels and sensory nerve fibers, the only cells in this tissue are fibroblasts, visible by their slender, violet-staining nuclei squeezed between bundles of collagen. This type of tissue has few blood vessels, so injured tendons and ligaments are slow to heal.

The vocal cords and some spinal ligaments are made of a dense regular connective tissue called **elastic tissue**. In addition to the densely packed collagen fibers, it exhibits branching elastic fibers and more fibroblasts. The fibroblasts have larger, more conspicuous nuclei than seen in most dense regular connective tissue. Elastic tissue also forms wavy sheets in large and medium arteries. When the heart pumps blood into the arteries, these sheets enable them to expand and relieve some of the pressure on smaller vessels downstream. When the heart relaxes, the arterial wall springs back and keeps the blood pressure from dropping too low between heartbeats. The importance of this elastic tissue becomes especially clear in diseases such as Marfan syndrome (see Deeper Insight 5.2) and arteriosclerosis, where the tissue is stiffened by lipid and calcium deposits (see Deeper Insight 19.4).

Dense irregular connective tissue (fig. 5.17) also has thick bundles of collagen and relatively little room for cells and ground substance, but the collagen bundles run in random-looking directions. This arrangement enables the tissue to resist unpredictable stresses. This tissue constitutes most of the dermis, where it binds the skin to the underlying muscle and connective tissue. It forms a protective capsule around organs such as the kidneys, testes, and spleen and a tough fibrous sheath around the bones, nerves, and most cartilages.

It is sometimes difficult to judge whether a tissue is areolar or dense irregular. In the dermis, for example, these tissues occur side by side, and the transition from one to the other isn't at all obvious (see fig. 5.8). A relatively large amount of clear space suggests areolar tissue, and thicker bundles of collagen and relatively little clear space suggest dense irregular connective tissue.

Fibrous connective tissue often forms a filler, or *interstitium*, around and between other structures such as blood vessels and gland ducts and within the walls of some organs. In some places, this interstitium is like a honeycomb of fluid-filled spaces supported by thick bundles of collagen. These aren't seen in prepared slides, where the spaces are empty and collapsed, and the collagen is densely packed as in figure 5.17; they were recently discovered in surgical patients by a new microscopic imaging technique. They're found especially in areas subject to frequent compression, such as the dermis of the skin, the bile duct, and walls of the digestive tract and urinary bladder. They drain into the lymph nodes and may be important as a route of cancer metastasis.

DEEPER INSIGHT 5.2

CLINICAL APPLICATION

Marfan Syndrome—A Connective Tissue Disease

*Marfan*¹⁷ *syndrome* is a hereditary defect in elastic fibers, usually resulting from a mutation in the fibrillin gene. Clinical signs of Marfan syndrome include hyperextensible joints, hernias of the groin, and visual problems resulting from abnormally elongated eyes and deformed lenses. People with Marfan syndrome typically show unusually tall stature, long limbs, spidery fingers, abnormal spinal curvature, and a protruding “pigeon breast.” More serious problems are weakened heart valves and arterial walls. The aorta, where blood pressure is highest, is sometimes enormously dilated close to the heart and may rupture. Marfan syndrome is present in about 1 out of 20,000 live births. About 80% of cases are hereditary, but 1 in 5 result from new, spontaneous prenatal mutations in the affected individual. Parents in which one partner has Marfan syndrome and the other doesn't have a 50% chance of transmitting it to any one of their children. With early diagnosis and recent advances in treatment, people with Marfan syndrome now have a life expectancy of about 70, close to the general population. Abraham Lincoln's tall, gangly physique and spindly fingers led some authorities to suspect that he had Marfan syndrome, but the evidence is inconclusive. Some star athletes have died at a young age of Marfan syndrome, including Olympic volleyball champion Flo Hyman (1954–86), who died at the age of 31 of a ruptured aorta during a game in Japan.

5.3c Adipose Tissue

Adipose tissue, or **fat**, is tissue in which adipocytes are the dominant cell type (**table 5.6** and **fig. 5.18**). Adipocytes may also occur singly or in small clusters in areolar tissue. The space between adipocytes is occupied by areolar tissue, reticular tissue, and blood capillaries.

Fat is the body's primary energy reservoir. The quantity of stored triglyceride and the number of adipocytes are quite stable in a person, but this doesn't mean stored fat is stagnant. New triglycerides are constantly synthesized and stored as others are hydrolyzed and released into circulation. Thus, there is a constant turnover of stored triglyceride, with an equilibrium between synthesis and hydrolysis, energy storage and energy use.

There are two kinds of fat in humans—white (or yellow) fat and brown fat. **White adipose tissue (WAT)**, or **white fat**, is the more abundant and is the most significant adipose tissue of the adult body. Its adipocytes are usually 70 to 120 μm in diameter, but may be five times as large in obese people. They have a single large, central globule of triglyceride. Their cytoplasm is restricted to a thin layer immediately beneath the plasma membrane, and the nucleus is pushed against the edge of the cell. Since the triglyceride is dissolved out by most histological techniques, fat cells in most specimens look empty and slightly shriveled, with a resemblance to chicken wire.

White fat provides thermal insulation, anchors and cushions such organs as the eyeballs and kidneys, and contributes to body contours such as the female breasts and hips. On average, women have more fat relative to body weight than men do. It helps to meet the caloric needs of pregnancy and nursing an infant, and having too little fat reduces female fertility. In addition to its insulation and energy-storage roles, WAT secretes hormones that help to regulate the body's energy metabolism. Some authorities regard WAT as an endocrine organ.

Brown adipose tissue (BAT), or **brown fat**, is found mainly in fetuses, infants, and children, but adults also have lesser deposits of it. It accounts for up to 6% of an infant's weight, and is concentrated especially in fat pads in the shoulders, upper back, and around the kidneys and heart. It stores lipid in the form of multiple globules rather than one large one. It gets its color from a high density of blood capillaries, more numerous mitochondria than WAT has, and especially, iron-containing enzymes in the mitochondria.

Brown fat is a heat-generating tissue that evolved in mammals as a protection from cold stress and hypothermia, especially in infants. Most mitochondria in the body oxidize organic fuels to transfer as much energy as possible to ATP, but the mitochondria of BAT release all that energy as heat instead. BAT is heavily innervated by the sympathetic nervous system, which is highly responsive to cold. These nerve fibers stimulate the mitochondria to break down stored lipid to warm the body.

This is especially crucial for infants for several reasons. They have a higher ratio of body surface area to volume and therefore lose heat more rapidly, especially through their relatively large heads. With an immature muscular system, infants up to 6 months old can't generate heat by shivering. Their nervous systems aren't yet mature enough to respond quickly to cold by such means as constricting dermal blood vessels to reduce heat loss through the skin. And, of course, they can't respond to cold as we do by putting on more clothing or moving to a warmer spot. Consequently, infants are highly vulnerable to hypothermia; brown fat is one of

TABLE 5.6

Adipose Tissue

(a)

(b)

FIGURE 5.18 White Adipose Tissue. Breast ($\times 100$). (a) Light micrograph. (b) Labeled drawing. **APR**

a: Dennis Strete/McGraw Hill

Microscopic appearance: Dominated by adipocytes—large, empty-looking cells with thin margins; tissue sections often very pale because of scarcity of stained cytoplasm; adipocytes shrunk; nucleus pressed against plasma membrane; blood vessels present

Representative locations: Subcutaneous fat beneath skin; breast; heart surface; mesenteries; surrounding organs such as kidneys and eyes

Functions: Energy storage; thermal insulation; heat production by brown fat; protective cushion for some organs; filling space, shaping body

their few defenses. Hibernating mammals such as bears also put on brown fat in preparation for winter.

▶▶▶ APPLY WHAT YOU KNOW

Why would infants and children have more need for brown fat than adults do? (Hint: Smaller bodies have a higher ratio of surface area to volume than larger bodies do.)

5.3d Cartilage

Cartilage is a relatively stiff connective tissue with a flexible rubbery matrix; you can feel its texture by folding and releasing the external ear or palpating the tip of your nose or the *thyroid cartilage* of the larynx (“Adam’s apple”). It is also easily seen in many grocery items—it is the milky-colored gristle at the ends of pork ribs and on chicken leg and breast bones, for example. Among other functions, cartilages shape and support the nose and ears and partially enclose the larynx (voice box), trachea (windpipe), and thoracic cavity.

Cartilage is produced by cells called **chondroblasts**¹⁸ (CON-dro-blasts), which secrete the matrix and surround themselves with it until they become trapped in little cavities called **lacunae**¹⁹ (la-CUE-nee). Once enclosed in lacunae, the cells are called **chondrocytes** (CON-dro-sites). Cartilage is devoid of blood capillaries, so nutrition and waste removal depend on solute diffusion through the stiff matrix. Because this is a slow process, chondrocytes have low rates of metabolism and cell division, and injured cartilage heals slowly.

The matrix is rich in glycosaminoglycans and contains collagen fibers that range from invisibly fine to conspicuously coarse. Differences in the fibers provide a basis for classifying cartilage into three types: *hyaline cartilage*, *elastic cartilage*, and *fibrocartilage* (shown in **table 5.7** and **figs. 5.19** through **5.21**).

Hyaline²⁰ **cartilage** (HY-uh-lin) is named for its clear, glassy appearance, which stems from the usually invisible fineness of its collagen fibers. **Elastic cartilage** is named for its conspicuous elastic fibers, and **fibrocartilage** for its coarse, readily visible bundles of collagen. Elastic cartilage and most hyaline cartilage are surrounded by a sheath of dense irregular connective tissue called the **perichondrium**²¹ (PERR-ih-CON-dree-um). A reserve population of chondroblasts between the perichondrium and cartilage contributes to cartilage growth throughout life. Perichondrium is lacking from fibrocartilage and some hyaline cartilage, such as the cartilaginous caps at the ends of the long bones.

5.3e Bone

Bone, or **osseous tissue** (**table 5.8**, **fig. 5.22**), is a hard, calcified connective tissue that composes the skeleton. The term *bone* has two meanings in anatomy—an entire organ such as the femur and mandible, or just the osseous tissue. Bones are composed of not only osseous tissue, but also cartilage, bone marrow, dense irregular connective tissue, and other tissue types.

There are two forms of osseous tissue: (1) **Spongy bone** fills the heads of the long bones and forms the middle layer of flat bones such as the sternum and cranial bones. Although it is calcified and hard, its delicate slivers and plates give it a spongy appearance (see **fig. 7.4a**). (2) **Compact (dense) bone** is a denser calcified tissue with no spaces visible to the naked eye. It forms the external surfaces of all bones, so spongy bone, when present, is always covered by a shell of compact bone.

Further differences between compact and spongy bone are described in chapter 7. Here, we examine only compact bone. Most specimens you study will probably be chips of dead, dried compact bone ground to microscopic thinness. In such preparations, the cells are absent but spaces reveal their former locations. Most compact bone is arranged in cylinders of tissue that surround **central (osteonic) canals**, which run longitudinally through the shafts of long bones such as the femur. Blood vessels and nerves travel through these canals. The bone matrix is deposited in **concentric lamellae**—onionlike layers around each canal. A central canal and its surrounding lamellae are called an **osteon**. Lacunae between the lamellae are occupied by mature bone cells, or **osteocytes**.²² Delicate channels called **canaliculi** radiate from each lacuna to its neighbors and allow the osteocytes to contact each other. The bone as a whole is covered by **periosteum** (PERR-ee-OSS-tee-um), a tough fibrous membrane similar to the perichondrium of cartilage.

About one-third of the dry weight of bone is collagen and glycosaminoglycans, which enable a bone to bend slightly under stress. Two-thirds of its weight is minerals (mainly calcium and phosphate salts) that enable bones to withstand compression by the weight of the body.

5.3f Blood

Blood (**table 5.9**, **fig. 5.23**) is a fluid connective tissue that travels through tubular blood vessels. Its primary function is to transport cells and dissolved matter from place to place. It may seem odd that a tissue as fluid as blood and another as rock hard as bone are both considered connective tissues, but they have more in common than first meets the eye. Like other connective tissues, blood is composed of more ground substance than cells. Its ground substance is the **blood plasma** and its cellular components are collectively called the **formed elements**. Another factor placing blood in the connective tissue category is that it is produced by the connective tissues of the bone marrow and lymphoid organs. Unlike other connective tissues, blood doesn’t exhibit fibers except when it clots.

The formed elements are of three kinds—erythrocytes, leukocytes, and platelets. **Erythrocytes**²³ (eh-RITH-ro-sites), or **red blood cells (RBCs)**, are the most abundant. In stained blood films, they look like pink discs with thin, pale centers and no nuclei. Erythrocytes transport oxygen and carbon dioxide. **Leukocytes**, or **white blood cells (WBCs)**, serve various roles in defense against infection and other diseases. They travel from one organ to another in the bloodstream and lymph but spend most of their lives in the connective tissues. Leukocytes are somewhat

a: Dennis Strete/McGraw Hill

Microscopic appearance (compact bone): Calcified matrix arranged in concentric lamellae around central canals; osteocytes in lacunae between adjacent lamellae; lacunae interconnected by delicate canaliculi

Representative location: Skeleton

Functions: Physical support of body; leverage for muscle action; protective enclosure of viscera; reservoir of calcium and phosphorus

TABLE 5.9

Blood

(a)

(b)

FIGURE 5.23 Blood Smear ($\times 1,000$). (a) Light micrograph. (b) Labeled drawing. **APR**

a: Ed Reschke/Stone/Getty Images

Microscopic appearance: Erythrocytes appear as pale pink discs with light centers and no nuclei; leukocytes are slightly larger, are much fewer, and have variously shaped nuclei, usually stained violet; platelets are cell fragments with no nuclei, about one-quarter the diameter of erythrocytes

Representative locations: Contained in heart and blood vessels

Functions: Transports gases, nutrients, wastes, chemical signals, and heat throughout body; provides defensive leukocytes; contains clotting agents to minimize bleeding; platelets secrete growth factors that promote tissue maintenance and repair

larger than erythrocytes and have conspicuous nuclei that usually appear violet in stained preparations. There are five kinds, distinguished partly by variations in nuclear shape: *neutrophils*, *eosinophils*, *basophils*, *lymphocytes*, and *monocytes*. Their individual characteristics are considered in detail in chapter 18. **Platelets** are small cell fragments scattered amid the blood cells. They are involved in clotting and other mechanisms for minimizing blood loss, and in secreting growth factors that promote blood vessel growth and maintenance.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

9. What features do most or all connective tissues have in common to set this class apart from nervous, muscular, and epithelial tissue?
10. List the cell and fiber types found in fibrous connective tissues and state their functional differences.
11. What substances account for the gelatinous consistency of connective tissue ground substance?
12. What is areolar tissue? How can it be distinguished from any other kind of connective tissue?
13. Discuss the difference between dense regular and dense irregular connective tissue as an example of the relationship between form and function.
14. Describe some similarities, differences, and functional relationships between hyaline cartilage and bone.
15. What are the three basic kinds of formed elements in blood, and what are their respective functions?

5.4 Nervous and Muscular Tissues—Excitable Tissues

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain what distinguishes excitable tissues from other tissues;
- b. name the cell types that compose nervous tissue;
- c. identify the major parts of a nerve cell;
- d. visually recognize nervous tissue from specimens or photographs;
- e. name the three kinds of muscular tissue and describe the differences between them; and
- f. visually identify any type of muscular tissue from specimens or photographs.

Excitability is a characteristic of all living cells, but it is developed to its highest degree in nervous and muscular tissues, which are therefore described as **excitable tissues**. The basis for their

excitation is an electrical charge difference (voltage) called the *membrane potential*, which occurs across the plasma membranes of all cells. Nervous and muscular tissues respond quickly to outside stimuli by means of changes in membrane potential. In nerve cells, these changes result in the rapid transmission of signals to other cells. In muscle cells, they result in contraction, or shortening of the cell.

5.4a Nervous Tissue

Nervous tissue (table 5.10, fig. 5.24) is specialized for communication by means of electrical and chemical signals. It consists of **neurons** (NOOR-ons), or nerve cells, and a much greater number of **neuroglia** (noo-ROG-lee-uh), or **glial cells** (GLEE-ul), which protect and assist the neurons. Neurons detect stimuli, respond quickly, and transmit coded information rapidly to other cells. Each neuron has a prominent **cell body** that houses the nucleus and most other organelles. This is the cell's center of genetic control and protein synthesis. Nerve cell bodies are usually round, ovoid, or stellate in shape. Extending from the cell body, there are usually multiple short, branched processes called **dendrites**,²⁴ which receive signals from other cells and conduct messages to the cell body; and a single, much longer **axon**, or **nerve fiber**, which sends outgoing signals to other cells. Some axons are more than a meter long and extend from the brainstem to the foot.

Glial cells constitute most of the volume of the nervous tissue. They are usually much smaller than neurons. There are six types of glial cells, described in chapter 12, which provide a variety of supportive, protective, and “housekeeping” functions for the nervous system. Although they communicate with neurons and each other, they don't transmit long-distance signals.

Nervous tissue is found in the brain and spinal cord (central nervous system), nerves, and ganglia, which are knotlike swellings in nerves where the nerve cell bodies outside the central nervous system are concentrated. Local variations in the structure of nervous tissue are described in chapters 12 to 16.

5.4b Muscular Tissue

Muscular tissue is specialized to contract when stimulated, and thus to exert a physical force on other tissues, organs, or fluids—for example, a skeletal muscle pulls on a bone, the heart contracts and expels blood, and the bladder contracts and expels urine. Not only do movements of the body and its limbs depend on muscle, but so do such processes as digestion, waste elimination, breathing, speech, and blood circulation. The muscles are also an important source of body heat.

There are three types of muscular tissue—*skeletal*, *cardiac*, and *smooth*—which differ in appearance, physiology, and function (as shown in table 5.11 and figs. 5.25 through 5.27). Any muscle cell can be called a **myocyte**. More specific terms are used, as you will see, to refer to the special characteristics of skeletal and cardiac muscle.

²⁴dendr = tree; ite = little

TABLE 5.10

Nervous Tissue

a: Ed Reschke/Photolibrary/Stone/Getty Images

Microscopic appearance: Most sections show a few large neurons, usually with rounded or stellate cell bodies and fibrous processes (axon and dendrites) extending from the cell bodies; neurons are surrounded by a greater number of much smaller glial cells, which lack dendrites and axons.

Representative locations: Brain, spinal cord, nerves, ganglia

Function: Internal communication

Skeletal muscle consists of long threadlike cells called **muscle fibers**. Most skeletal muscle is attached to bones, but there are exceptions in the tongue, upper esophagus, some facial muscles, and some **sphincter**²⁵ (SFINK-tur) muscles (muscular rings or cuffs that open and close body passages). Skeletal muscle is described as striated and voluntary. The first term refers to alternating light and dark bands, or **striations** (stry-AY-shuns), created by the overlapping pattern of cytoplasmic protein filaments that cause muscle contraction. The second term, *voluntary*, refers to the fact that we usually have conscious control over skeletal muscle. Skeletal muscle fibers exhibit multiple nuclei pressed against the inside of the plasma membrane. Muscle fibers have an astonishing 30 to 77 nuclei per millimeter, and some of the longest fibers in the human muscular system are up to 30 cm long—suggesting they have over 20,000 nuclei in one cell! A more typical muscle fiber is about 3 cm long and has perhaps 900 nuclei or so.

Cardiac muscle is limited to the heart. Its cells, called **cardiomyocytes**,²⁶ are striated but differ from skeletal muscle in other features. They are much shorter and are branched or notched at the ends. They usually contain only one nucleus, which is located near the center and often surrounded by a light-staining region of glycogen; some cells have two. Cardiomyocytes are joined end to end by junctions called **intercalated discs**²⁷ (in-TUR-kuh-LAY-ted). Mechanical connections in these discs keep the cells from pulling apart when the heart contracts. Electrical junctions in the discs allow a wave of electrical excitation to travel rapidly from cell to cell so all the cardiomyocytes of a heart chamber are stimulated and contract almost simultaneously. Intercalated discs appear as dark transverse lines separating each cell from the next. They may be only faintly visible, however, unless the tissue has been specially stained for them. Cardiac muscle is considered *involuntary* because it is not usually under conscious control; it contracts even if all nerve connections to it are severed.

Smooth muscle lacks striations and is involuntary. Smooth muscle myocytes are fusiform and relatively short. They have only one, centrally placed nucleus. Small amounts of smooth muscle are found in the iris of the eye and in the skin, but most of it, called **visceral muscle**, forms layers in the walls of the digestive, respiratory, and urinary tracts; blood vessels; the uterus; and other viscera. In locations such as the esophagus and small intestine, smooth muscle forms adjacent layers, with the cells of one layer encircling the organ and the cells of the other layer running longitudinally. When the circular smooth muscle contracts, it propels contents such as food through the organ. By regulating the diameter of blood vessels, smooth muscle is very important in controlling blood pressure and flow. Both smooth and skeletal muscle form sphincters that control the emptying of the bladder and rectum.

▶▶▶ APPLY WHAT YOU KNOW

How does the meaning of the word fiber differ in the following uses: muscle fiber, nerve fiber, and connective tissue fiber?

²⁵sphinc = squeeze, bind tightly

²⁶cardio = heart; myo = muscle; cyte = cell

²⁷inter = between; calated = inserted

APR a: Dennis Strete/McGraw Hill Microscopic appearance: Short fusiform cells overlapping each other; nonstriated; one nucleus per cell, centrally located Representative locations: Usually found as sheets of tissue in walls of blood vessels and viscera such as the digestive tract; also in iris and associated with hair follicles; involuntary sphincters of urethra and anus Functions: Swallowing; contractions of stomach and intestines; expulsion of feces and urine; labor contractions; control of blood pressure and flow; control of respiratory airflow; control of pupillary diameter; erection of hairs; under involuntary control

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

16. What do nervous and muscular tissue have in common? What is the primary function of each?
17. What kinds of cells compose nervous tissue, and how can they be distinguished from each other?
18. Name the three kinds of muscular tissue, describe how to distinguish them from each other in microscopic appearance, and state a location and function for each.

5.5 Cellular Junctions, Glands, and Membranes

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the junctions that hold cells and tissues together;
- b. describe or define different types of glands;
- c. describe the typical anatomy of a gland;
- d. name and compare different modes of glandular secretion; and
- e. describe the types and composition of the body's membranes.

5.5a Cellular Junctions

Most cells—except for blood cells, macrophages, and metastatic cancer cells—must be anchored to each other and to the matrix if they're to grow and divide normally. The connections between one cell and another are called **cellular junctions**. They enable the cells to resist stress, communicate with each other, and control the movement of substances through tissues. Without them, cardiac muscle cells would pull apart when they contracted, and every swallow of food might scrape away the lining of your esophagus. The main types of cellular junctions are shown in **figure 5.28**.

Tight Junctions

A **tight junction** completely encircles an epithelial cell near its apical surface and joins it tightly to the neighboring cells, somewhat like the plastic harness on a six-pack of soda cans. At a tight junction, the plasma membranes of two adjacent cells come very close together and are linked by transmembrane cell-adhesion proteins. These zipperlike interlocking proteins seal off the intercellular space and make it difficult or impossible for substances to pass between cells.

In the stomach and intestines, tight junctions prevent digestive juices from seeping between epithelial cells and digesting the underlying connective tissue. They also help to prevent bacteria from invading the tissues, and they ensure that most nutrients pass *through* the epithelial cells and not *between* them. In addition, some membrane proteins function in the apical domain of the cell,

and others in the lateral or basal domains; tight junctions limit how far drifting proteins can travel and keep them segregated in the appropriate domains of the membrane where they are needed to perform their tasks.

Desmosomes

A **desmosome**²⁸ (DEZ-mo-some) is a patch that holds cells together somewhat like the snap on a pair of jeans. Desmosomes are not continuous and can't prevent substances from passing around them and going between the cells, but they serve to keep cells from pulling apart and enable a tissue to resist mechanical stress. Desmosomes are common in the epidermis, the epithelium of the uterine cervix, other epithelia, and cardiac muscle. Hooklike J-shaped proteins arise from the cytoskeleton, approach the cell surface from within, and penetrate into a thick protein plaque on the inner face of the plasma membrane; then the short arm of the J turns back into the cell—thus anchoring the cytoskeleton to the membrane plaque. Proteins of the plaque are linked to transmembrane proteins and these, in turn, are linked to transmembrane proteins of the next cell, forming a zone of strong cell adhesion. Each cell mirrors the other and contributes half of the desmosome. Such connections create a strong structural network that binds cells together throughout the tissue. The basal cells of an epithelium are similarly linked to the underlying basement membrane by half-desmosomes called **hemidesmosomes**, so an epithelium cannot easily peel away from the underlying tissue.

▶▶▶ APPLY WHAT YOU KNOW

Why would desmosomes not be suitable as the sole type of cell junction between epithelial cells of the stomach?

Gap Junctions

A **gap (communicating) junction** is formed by a *connexon*, which consists of six transmembrane proteins arranged in a ring, somewhat like the segments of an orange, surrounding a water-filled channel. Ions, glucose, amino acids, and other small solutes can pass directly from the cytoplasm of one cell into the next through the channel. In the embryo, nutrients pass from cell to cell through gap junctions until the circulatory system forms and takes over the role of nutrient distribution. In cardiac muscle and most smooth muscle, gap junctions allow electrical excitation to pass directly from cell to cell so that the cells contract in near unison. (Gap junctions are absent from skeletal muscle.) In the lens and cornea of the eye, which lack blood vessels, gap junctions allow nutrients and other material to pass from cell to cell.

5.5b Glands

A **gland** is a cell or organ that secretes substances for use elsewhere in the body or for elimination as waste. The gland product may be something synthesized by its cells (such as digestive enzymes) or something removed from the tissues and modified by the gland (such as urine and bile pigments). The product is called a

²⁸*desmo* = band, bond, ligament; *som* = body

FIGURE 5.28 Structure of Four Kinds of Cellular Junctions. (a) Tight junction. (b) Desmosome. (c) Gap junction. (d) Hemidesmosome between cell and basement membrane.

? Which of these junctions allows material to pass from one cell directly into the next?

secretion if it is useful to the body (such as an enzyme or hormone) and an **excretion** if it is a waste product (such as urine and bile). Glands are composed mostly of epithelial tissue, but usually have a supportive connective tissue framework and capsule.

Endocrine and Exocrine Glands

Glands are classified as endocrine or exocrine. Both types originate as invaginations of a surface epithelium (**fig. 5.29**). **Exocrine²⁹ glands** (EC-so-crin) usually maintain their contact with the surface by way of a **duct**, an epithelial tube that conveys their secretion to the surface. The secretion may be released to the body surface, as in the case of sweat, mammary, and tear glands. More often, however, it is released into the cavity (lumen) of another organ such as the mouth or intestine; this is the case with salivary glands, the liver, and the pancreas.

Endocrine³⁰ glands lose contact with the surface during their development and thus have no ducts. They do, however, have a high density of blood capillaries and secrete their products directly into the blood (**fig. 5.30a**). The secretions of endocrine glands, called *hormones*, function as chemical messengers to stimulate cells elsewhere in the body. Endocrine glands include the pituitary, thyroid, and adrenal glands.

Unicellular glands are secretory cells found in an epithelium that is predominantly nonsecretory. They can be endocrine or exocrine. For example, the respiratory tract, which is lined mainly by ciliated cells, also has a liberal scattering of exocrine goblet cells (see **figs. 5.6 and 5.7**). The stomach and small intestine have abundant endocrine cells, which secrete hormones that regulate digestion.

Endocrine glands are the subject of chapter 17 and are not further considered here.

²⁹*exo* = out; *crin* = to separate, secrete

³⁰*endo* = in, into; *crin* = to separate, secrete

FIGURE 5.29 Development of Exocrine and Endocrine Glands. (a) An exocrine gland begins with epithelial cells proliferating into the connective tissue below. A form of cell death called *apoptosis* hollows out the core and creates a duct to the surface. The gland remains connected to the surface for life by way of this duct and releases its secretions onto the epithelial surface. (b) An endocrine gland begins similarly, but the cells connecting it to the surface degenerate while the secretory tissue becomes infiltrated with blood capillaries. The secretory cells secrete their products (hormones) into the blood.

Exocrine Gland Structure

Multicellular exocrine glands such as the pancreas and salivary glands are usually enclosed in a fibrous **capsule** (fig. 5.30b). The capsule often gives off extensions called **septa** (singular, *septum*), or **trabeculae** (trah-BEC-you-lee), that divide the interior of the gland into compartments called **lobes**, which are visible to the naked eye. Finer connective tissue septa may further subdivide each lobe into microscopic **lobules**. Blood vessels, nerves, and the gland's own ducts generally travel through these septa. The connective tissue framework of the gland, called its **stroma**, supports and organizes the glandular tissue. The cells that perform the tasks of synthesis and secretion are collectively called the **parenchyma** (pa-REN-kih-muh). This is typically simple cuboidal or simple columnar epithelium.

Exocrine glands are classified according to their “architecture”—the branching of their ducts and the appearance and extent of their secretory portions (fig. 5.31). They are called **simple** if they have a single unbranched duct and **compound** if they have a branched duct. If the duct and secretory portion are of uniform diameter, the gland is called **tubular**. If the secretory cells form a dilated sac, the gland is called **acinar** and the sac is an **acinus**³¹ (ASS-ih-nus), or **alveolus**³² (AL-vee-OH-lus) (fig. 5.30c). A gland with secretory

cells in both the tubular and acinar portions is called a **tubuloacinar** (tubuloalveolar) gland.

Types of Secretions

Glands are classified not only by their structure but also by the nature of their secretions. **Serous glands** (SEER-us) produce relatively thin, watery fluids such as perspiration, milk, tears, and digestive juices. **Mucous glands**, found in the oral and nasal cavities among other places, secrete a glycoprotein called **mucin** (MEW-sin). After it is secreted, mucin absorbs water and forms sticky **mucus**. Goblet cells are unicellular mucous glands. (Note that *mucus*, the secretion, is spelled differently from *mucous*, the adjective form of the word.) **Mixed glands**, such as the two pairs of salivary glands in the chin, contain both serous and mucous cells and produce a mixture of the two types of secretions.

Modes of Secretion

Exocrine glands are classified into *eccrine*, *apocrine*, and *holocrine* types according to how they release their secretions. **Eccrine**³³ glands (EC-rin), also called **merocrine**³⁴ glands (MERR-oh-crin), release their products by means of exocytosis. These include the tear glands, salivary glands, pancreas, and most others. Mammary

³¹acinus = berry

³²alveol = cavity, pit

³³ec = ex = out; crin = to separate, secrete

³⁴mero = part; crin = to separate, secrete

FIGURE 5.30 General Structure of Endocrine and Exocrine Glands. (a) Endocrine glands have no ducts but have a high density of blood capillaries and secrete their products (hormones) directly into the bloodstream. (b) Exocrine glands usually have a system of ducts, which often follow connective tissue septa, until their finest divisions end in saccular acini of secretory cells. (c) Detail of an acinus and the beginning of a duct.

? What membrane transport process are the cells of the acinus in (c) carrying out? (Review section 3.3f)

glands secrete milk sugar (lactose) and proteins (casein, lactalbumin) by this method (fig. 5.32a), but secrete the milk fat by another method called **apocrine**³⁵ secretion (fig. 5.32b). In this process, lipids coalesce from the cytosol into a droplet that buds from the cell surface, covered by a layer of plasma membrane and a very thin film

of cytoplasm. Sweat glands of the axillary (armpit) region were once thought to use the apocrine method as well. Closer study showed this to be untrue; they are eccrine, but they're nevertheless different from other merocrine glands in function and histological appearance (see figure 6.11) and are still referred to as apocrine sweat glands.

In **holocrine**³⁶ glands, cells accumulate a product and then the entire cell disintegrates, becoming the secretion instead of releasing one (fig. 5.32c). Holocrine secretions tend to be relatively thick and oily, composed of cell fragments and the substances the cells had synthesized before disintegrating. Only a few glands use this method, such as the oil-producing glands of the scalp and other areas of skin, and certain glands of the eyelid.

5.5c Membranes

Atlas A (section A.3) describes the major body cavities and the membranes that line them and cover their viscera. We now consider some histological aspects of these membranes. Membranes may be composed of epithelial tissue only; connective tissue only; or epithelial, connective, and muscular tissue.

The largest membrane of the body is the **cutaneous membrane**—or more simply, the skin (detailed in chapter 6). It consists of a stratified squamous epithelium (epidermis) resting on a layer of connective tissue (dermis). Unlike the other membranes to be considered, it is relatively dry. It resists dehydration of the body and provides an inhospitable environment for the growth of infectious organisms.

The two principal kinds of internal membranes are mucous and serous membranes. **Mucous membranes (mucosae)** (fig. 5.33a) line passages that open to the exterior environment: the digestive, respiratory, urinary, and reproductive tracts. A mucous membrane consists of two to three layers: (1) an epithelium; (2) an areolar connective tissue layer called the **lamina propria**³⁷ (LAM-ih-nuh PRO-pree-uh); and (3) often a layer of smooth muscle called the **muscularis mucosae** (MUSK-you-LAIR-iss mew-CO-see). Mucous membranes have absorptive, secretory, and protective functions. They are often covered with mucus secreted by goblet cells, multicellular mucous glands, or both. The mucus traps bacteria and foreign particles, which keeps them from invading the tissues and aids in their removal from the body. The epithelium of a mucous membrane may also include absorptive, ciliated, and other types of cells.

A **serous membrane (serosa)** is composed of a simple squamous epithelium resting on a thin layer of areolar connective tissue (fig. 5.33b). Serous membranes produce watery **serous fluid**, which arises from the blood and derives its name from the fact that it is similar to blood serum in composition. Serous membranes line the insides of some body cavities and form a smooth outer surface on some of the viscera, such as the digestive tract. The pleurae, pericardium, and peritoneum described in atlas A are serous membranes. The epithelial layer of a serous membrane is called **mesothelium**.

The circulatory system is lined with a simple squamous epithelium called **endothelium**, derived from mesoderm. The endothelium rests on a thin layer of areolar tissue, which often rests in turn on an elastic sheet. Collectively, these tissues make

³⁵apo = from, off, away; crin = to separate, secrete

³⁶holo = whole, entire; crin = to separate, secrete

³⁷lamina = layer; propria = of one's own

FIGURE 5.31 Some Types of Exocrine Glands. (a) A simple coiled tubular gland such as a sweat gland. (b) A compound acinar gland such as the mammary gland. (c) A compound tubuloacinar gland such as the pancreas. These are only a few examples of the 10 or so types of gland architecture.

? Predict and sketch the appearance of a simple acinar gland.

FIGURE 5.32 The Three Modes of Exocrine Secretion. (a) Eccrine secretion in a cell of the mammary gland, secreting milk sugar (lactose) and proteins (casein, lactalbumin) by exocytosis. (b) Apocrine secretion of fat by a cell of the mammary gland. Fat droplets coalesce in the cytosol, then bud from the cell surface with a thin coat of cytoplasm and plasma membrane. (c) Holocrine secretion by a sebaceous (oil) gland of the scalp. In this method, entire gland cells break down and become the secretion (sebum).

? Which of these three glands would require the highest rate of mitosis? Why?

FIGURE 5.33 Histology of Mucous and Serous Membranes. (a) A mucous membrane such as the inner lining of the trachea. (b) A serous membrane such as the external surface of the small intestine.

up a membrane called the *tunica interna* of the blood vessels and *endocardium* of the heart.

The foregoing membranes are composed of two to three tissue types. By contrast, some membranes composed only of connective tissue include the *dura mater* around the brain, *synovial membranes* that enclose joints of the skeletal system, and the *periosteum* that covers each bone. Some membranes composed only of epithelium include the anterior surfaces of the lens and cornea of the eye. All of these are described in later chapters.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

19. Compare the structure of tight junctions and gap junctions. Relate their structural differences to their functional differences.
20. Distinguish between a simple gland and a compound gland, and give an example of each. Distinguish between a tubular gland and an acinar gland, and give an example of each.
21. Contrast the eccrine, apocrine, and holocrine methods of secretion, and name a gland product produced by each method.
22. Describe the differences between a mucous and a serous membrane.
23. Name the layers of a mucous membrane, and state which of the four primary tissue classes composes each layer.

5.6 Tissue Growth, Development, Repair, and Degeneration

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name and describe the modes of tissue growth;
- b. define *adult* and *embryonic stem cells* and their varied degrees of developmental plasticity;
- c. name and describe the ways that a tissue can change from one type to another;
- d. name and describe the modes and causes of tissue shrinkage and death; and
- e. name and describe the ways the body repairs damaged tissues.

5.6a Tissue Growth

Tissues grow because their cells increase in number or size. Most embryonic and childhood growth occurs by **hyperplasia**³⁸ (HY-pur-PLAY-zhuh)—tissue growth through cell multiplication. Skeletal muscles and adipose tissue grow, however, through **hypertrophy**³⁹ (hy-PUR-truh-fee)—the enlargement of preexisting cells. Even a very muscular or obese adult has essentially the same number of muscle fibers or adipocytes as he or she had in late adolescence, but the cells may be substantially larger. **Neoplasia**⁴⁰ (NEE-oh-PLAY-zhuh) is the development of a tumor (*neoplasm*)—whether benign or malignant—composed of abnormal, nonfunctional tissue.

5.6b Tissue Development

You have studied the form and function of more than two dozen discrete types of human tissue in this chapter. You shouldn't leave this subject, however, with the impression that once these tissue types are established, they never change. Tissues are, in fact, capable of changing from one type to another within certain limits. Most obviously, unspecialized tissues of the embryo develop into more diverse and specialized types of mature tissue—mesenchyme to cartilage and bone, for example. This development of a more specialized form and function is called **differentiation**.

Some tissues can undergo **metaplasia**,⁴¹ a change from one type of mature tissue to another. For example, the vagina of a prepubescent girl is lined with a simple cuboidal epithelium. At puberty, it changes to a stratified squamous epithelium, better adapted to the future demands of intercourse and childbirth. The long bones of a child are filled with blood-producing red bone marrow, but by adulthood, most of this changes to adipose tissue. In smokers, the pseudostratified columnar epithelium of the bronchi may transform into a stratified squamous epithelium.

▶▶▶ APPLY WHAT YOU KNOW

What functions of a ciliated pseudostratified columnar epithelium could not be served by a stratified squamous epithelium? In light of this, what might be some consequences of bronchial metaplasia in heavy smokers?

5.6c Stem Cells

The growth and differentiation of tissues depend upon a supply of reserve **stem cells**. These are undifferentiated cells that are not yet performing any specialized function, but have the potential to differentiate into one or more types of mature functional cells, such as liver, brain, cartilage, or skin cells. Such cells have various degrees of **developmental plasticity**, or diversity of mature cell types to which they can give rise.

There are two types of stem cells: embryonic and adult. **Embryonic stem cells (ESCs)** compose the early human embryo

FIGURE 5.34 The Morula Stage of Human Development. This stage consists of about 16 to 32 totipotent stem cells with unlimited developmental plasticity.

Dr. Yorgos Nikas/Science Photo Library/Getty Images

(fig. 5.34). In the early stages of development, they're called **totipotent stem cells** because they have the potential to develop into any type of fully differentiated human cell—not only cells of the later embryonic, fetal, or adult body, but also cells of the temporary structures of pregnancy, such as the placenta and amniotic sac. Totipotency is unlimited developmental plasticity. About 4 days after fertilization, the developing embryo enters the *blastocyst* stage. The blastocyst is a hollow ball with an *outer cell mass* that helps form the placenta and other accessory organs of pregnancy, and an *inner cell mass (embryoblast)* that becomes the embryo itself (see fig. 29.4). Cells of the inner cell mass are called **pluripotent stem cells**; they can still develop into any cell type of the embryo, but not into the accessory organs of pregnancy. Thus their developmental plasticity is already somewhat limited.

Adult stem cells (ASCs) occur in small numbers in mature organs and tissues throughout a person's life. The name doesn't mean they're limited to adult persons; they are present throughout most of life from the fetus through old age. Typically an adult stem cell divides mitotically; one of its daughter cells remains a stem cell and the other one differentiates into a mature specialized cell. The latter cell may replace another that has grown old and died, contribute to the development of growing organs (as in a child), or help to repair damaged tissue. Some adult stem cells are **multipotent**—able to develop into two or more different cell lines, but not just any type of body cell. Certain multipotent bone marrow stem cells, for example, can give rise to red blood cells, five kinds of white blood cells, and platelet-producing cells. **Unipotent** stem cells have the most limited plasticity, as they can produce only one mature cell type. Examples include the cells that give rise to sperm, eggs, and keratinocytes (the majority cell type of the epidermis).

³⁸hyper = excessive; plas = growth

³⁹hyper = excessive; trophy = nourishment

⁴⁰neo = new; plas = form, growth

⁴¹meta = change; plas = form, growth

DEEPER INSIGHT 5.3

CLINICAL APPLICATION

Stem-Cell Therapy

Cell biologists, clinicians, and hopeful patients look to stem cells as a possible treatment for diseases arising from the loss of functional tissue. It would be ideal if adult stem cells could be used to restore lost tissues, but their developmental potential is too limited to be of very much clinical use. In addition, they're present in very small numbers and difficult to harvest from a tissue and culture in the quantities needed for therapy.

In principle, embryonic stem cells (ESCs), with their greater developmental plasticity, could overcome these shortcomings. ESCs are obtained from surplus embryos of about 16 to 32 cells (fig. 5.34) produced by *in vitro* fertilization (IVF) clinics, putting them to good use instead of the usual practice of discarding them. This issue remains controversial, but that has been defused to some extent. In 2006, Japanese cell biologist Shinya Yamanaka succeeded in a technique for stimulating adult stem cells to go backward down their developmental pathway and become pluripotent once again. He named the resulting cells **induced pluripotent stem cells (iPSCs)**. In the most optimistic scenarios, stem cells harvested from a person's skin or bone marrow might be induced to "back up" and go down new developmental pathways to produce cells of any desired type—cardiac, nervous, retinal, pancreatic, dental, or others. This has opened the door to hopes of regenerating many kinds of desired tissue from adult stem cells without the ethical and political issues of using embryonic cells.

As of 2020, the World Health Organization recognized 3,000 registered stem-cell clinical trials under way worldwide. Some of the diseases receiving the greatest attention are Parkinson disease, multiple sclerosis, amyotrophic lateral sclerosis, spinal cord injury, macular

degeneration, diabetes mellitus, and dental and other oral diseases. Unfortunately, producing iPSCs is a slow, tedious, costly process with a low success rate. Questions remain as to whether implanted stem cells may lodge in the wrong place in the body or grow into tumors instead of healthy functional tissue. Science has a long way to go, yet, in making stem-cell therapy effective, safe, efficient, and affordable for patients.

Stem cells have proven their value as "workhorses" of laboratory research in mechanisms of disease, toxicity screening, and drug testing. So far, however, the only therapies proven safe and effective, and approved by the U.S. Food and Drug Administration, are treatments using bone marrow and umbilical cord blood for certain leukemias and other blood- and immune-related diseases. Typically, the lag from a medical discovery to clinical use is about 20 years, and stem-cell therapy may be no exception. We could be in for a long wait to see if stem-cell technology will yield wider applications.

Meanwhile, unfortunately, fraudulent stem-cell "clinics" have sprung up around the world charging vulnerable people tens of thousands of dollars (in nonrefundable cash, of course) for worthless and even life-threatening treatments. Such reports have emerged because a patient was blinded by supposed stem-cell injections into the eyes and because stem cells injected into another patient developed into a spinal tumor. The FDA is attempting to crack down on illegal treatments in the United States, but many vulnerable patients continue to be victimized by illicit providers not only there but in Mexico, South America, India, East Asia, and elsewhere.

Both embryonic and adult stem cells have enormous potential for therapy, but advances in the field have been slowed both by technical difficulties and controversy over the use of embryonic cells (see Deeper Insight 5.3).

5.6d Tissue Repair

Damaged tissues can be repaired in two ways: *regeneration* or *fibrosis*. **Regeneration** is the replacement of dead or damaged cells by the same type of cells as before; it restores normal function to the organ. Most skin injuries (cuts, scrapes, and minor burns) heal by regeneration. The liver also regenerates remarkably well. **Fibrosis** is the replacement of damaged tissue with scar tissue, composed mainly of collagen produced by fibroblasts. Scar tissue helps to hold an organ together, but it doesn't restore normal function. Examples include the healing of severe cuts and burns, the healing of muscle injuries, and scarring of the lungs in tuberculosis.

Figure 5.35 illustrates the following stages in the healing of a cut in the skin, where both regeneration and fibrosis are involved:

- 1 Severed blood vessels bleed into the cut. Mast cells and cells damaged by the cut release histamine, which dilates blood vessels, increases blood flow to the area, and makes blood capillaries more permeable. Blood plasma seeps into the wound, carrying antibodies and clotting proteins.

- 2 A blood clot forms in the tissue, loosely knitting the edges of the cut together and inhibiting the spread of pathogens from the site of injury into healthy tissues. The surface of the blood clot dries and hardens in the air, forming a scab that temporarily seals the wound and blocks infection. Beneath the scab, macrophages begin to phagocytize and digest tissue debris.
- 3 New blood capillaries sprout from nearby vessels and grow into the wound. The deeper portions of the clot become infiltrated by capillaries and fibroblasts and transform into a soft mass called **granulation tissue**. Macrophages remove the blood clot while fibroblasts deposit new collagen to replace it. This *fibroblastic (reconstructive) phase* of repair begins 3 to 4 days after the injury and lasts up to 2 weeks.
- 4 Surface epithelial cells around the wound multiply and migrate into the wounded area, beneath the scab. The scab loosens and eventually falls off, and the epithelium grows thicker. Thus, the epithelium *regenerates* while the underlying connective tissue undergoes *fibrosis*, or scarring. Capillaries withdraw from the area as fibrosis progresses. The scar tissue may or may not show through the epithelium, depending on the severity of the wound. The wound may exhibit a depressed area at first, but this is often filled in by continued fibrosis and remodeling from below, until the scar becomes unnoticeable. This *remodeling (maturation) phase* of tissue repair begins several weeks after injury and may last as long as 2 years.

FIGURE 5.35 Stages in the Healing of a Skin Wound.

FIGURE 5.36 Dry Gangrene of the Foot Caused by Diabetes Mellitus.

William Archibald/CDC

5.6e Tissue Degeneration and Death

Atrophy⁴² (AT-ro-fee) is the shrinkage of a tissue through a loss in cell size or number. It results from both normal aging (*senile atrophy*) and lack of use of an organ (*disuse atrophy*). Muscles that are not exercised exhibit disuse atrophy as their cells become smaller. This was a serious problem for the first astronauts who participated in prolonged microgravity space flights. Upon return to normal gravity, they were sometimes too weak from muscular atrophy to walk. Space stations and shuttles now include exercise equipment to maintain the crew's muscular condition. Disuse atrophy also occurs when a limb is immobilized in a cast or by paralysis, or a person is confined to bed or a wheelchair by an illness or disability.

Necrosis⁴³ (neh-CRO-sis) is pathological tissue death due to trauma, toxins, infection, and so forth; infarction and gangrene are two types of necrosis. **Infarction** is the sudden death of tissue, such as cardiac muscle (*myocardial infarction*) or brain tissue (*cerebral infarction*), that occurs when its blood supply is cut off. **Gangrene** is tissue necrosis resulting from infection or an

obstructed blood supply. *Dry gangrene* often occurs in people with diabetes, especially in the feet. It is characterized by dry, shrunk skin with bluish-purple, brown, or black discoloration (fig. 5.36). A lack of sensation due to diabetic nerve damage can make a person oblivious to injury and infection, and poor blood circulation due to diabetic arterial damage results in slow healing and rapid spread of infection. This often necessitates the amputation of toes, feet, or legs. A **decubitus ulcer** (bed sore or **pressure sore**) is a form of dry gangrene that occurs when immobilized persons, such as those confined to a hospital bed or wheelchair, are unable to move, and continual pressure on the skin cuts off blood flow to an area. Pressure sores occur most often in places where a bone comes close to the body surface, such as the hips, sacral region, and ankles. Here, the thin layer of skin and connective tissue is especially prone to compression between the bone and a bed or wheelchair.

Wet gangrene typically occurs in internal organs and involves neutrophil invasion, liquefaction of the tissue, pus, and a foul odor. It can result from appendicitis or an obstructed colon, for example. *Gas gangrene* is necrosis of a wound resulting from infection with certain bacteria of the genus *Clostridium*, usually introduced when a wound is contaminated with soil. The disorder is named for bubbles of gas (mainly hydrogen) that accumulate in the tissues. This is a deadly condition that requires immediate intervention, often including amputation.

Cells dying by necrosis usually swell, exhibit *blebbing* (bubbling) of their plasma membranes, and then rupture. The cell contents released into the tissues trigger an inflammatory response in which macrophages phagocytize the cellular debris.

Apoptosis⁴⁴ (AP-op-TOE-sis), or **programmed cell death**, is often the normal death of cells that have completed their function and best serve the body by dying and getting out of the way. Cells can be induced to undergo apoptosis in some pathological conditions, however. Cells undergoing apoptosis shrink and are quickly phagocytized by macrophages and other cells. The cell contents never escape, so there is no inflammatory response. Although billions of cells die every hour by apoptosis, they are engulfed so quickly that they're almost never seen except within macrophages.

Apparently, nearly every cell has a built-in "suicide program" that enables the body to dispose of it when necessary. In some cases, an extracellular suicide signal binds to a receptor protein in the plasma membrane, which then activates enzymes that degrade the cell's DNA and proteins. In other cases, cells seem to undergo apoptosis automatically if they stop receiving growth factors from other cells. For example, in embryonic development we produce about twice as many neurons as we need. Those that make connections with target cells survive, while the excess neurons die for lack of *nerve growth factor*. Apoptosis also dissolves the webbing between the fingers and toes during embryonic development; it frees the earlobe from the side of the head in people with the genotype for detached earlobes; and it causes shrinkage of the breasts after lactation ceases.

⁴²*a* = without; *trophy* = nourishment

⁴³*necr* = death; *osis* = process

⁴⁴*apo* = away; *ptosis* = falling

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

24. Distinguish between differentiation and metaplasia.
25. Tissues can grow through an increase in cell size or cell number. What are the respective terms for these two kinds of growth?
26. Distinguish between atrophy, necrosis, and apoptosis, and describe a circumstance under which each of these forms of tissue loss may occur.
27. Distinguish between regeneration and fibrosis. Which process restores normal cellular function? What good is the other process if it does not restore function?

**DEEPER INSIGHT 5.4****CLINICAL APPLICATION****Regenerative Medicine**

As the population ages while science progresses in knowledge and technical skill, people look to the medical community with hopes of repairing or replacing body parts that are damaged, lost, defective from birth, or worn-out by age. Is it possible to repair brain or heart tissue; or a nose, ear, or finger; or even larger body parts lost to injury? The science of **regenerative medicine**, still in its infancy, seeks to do just that.

One of its approaches is **tissue engineering**—growing tissues and organs in the laboratory, ideally from the patient's own cells, and implanting them into the body. To produce something like a blood vessel or bronchus, tissue engineers start with an organ from a donor body and *decellularize* it—strip it of all living cells, leaving only its collagenous connective tissue framework, or scaffold. While preserving the shape and mechanical properties of the organ to be replaced, this cell-free scaffold eliminates the likelihood of immune rejection by the patient to receive it. It is then seeded with cells from the patient's body, such as chondrocytes, fibroblasts, or keratinocytes. The product is maintained in an incubator called a *bioreactor*, which provides nutrients, oxygen, and growth factors while the cells repopulate the scaffold. Some treatments use synthetic polymer scaffolds and even artificial organs produced by 3D inkjet bioprinters. One of the most daunting problems in growing artificial organs is producing the microvascular blood supply needed to sustain an organ such as a liver. Another is to induce the necessary nerve growth to control a bioengineered organ such as a urinary bladder. Without this, one might “succeed” only in giving the patient a dysfunctional organ.

Tissue engineering has succeeded in the laboratory in producing liver, bone, cartilage, ureter, tendon, blood vessels, intestine, insulin-secreting pancreatic islets, breast tissue, and even a beating rodent heart. “Bench to bedside” translation to the clinic and real patients is a more difficult matter. Early successes, however, include nasofacial reconstruction, engineered skin for covering burns and diabetic foot ulcers, repair of damaged knee cartilages, and even urinary bladders grown from patients' own cells and transplanted into their bodies. Preclinical trials are underway on producing bioengineered blood vessels for coronary bypass surgery, and hopes for future development include heart valves and patches of cardiac muscle.

In another innovative approach to tissue engineering, scientists have built tiny microdevices called *organs-on-a-chip*, or *organ chips*, that integrate human cells onto a membrane that mimics the extracellular environment. This technique has produced model organs about the size of computer memory sticks with the microstructures and functions of hearts, lungs, intestines, kidneys, skin, bone marrow, and brains. Organ chip technology accelerates the often lengthy path of drug development and testing, and is an alternative to animal testing, reducing the need for animals used in research, as well as the waste of time and resources on animal test results that don't carry over to human tissues. This technology also offers the possibility of testing drugs and therapies on a patient's own cells to personalize treatment.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

5.1 The Study of Tissues

1. Two names for the branch of biology concerned with tissue structure
2. The four primary tissue classes that constitute the body

3. The roles of cells, matrix, fibers, and ground substance in tissue composition, and how these terms relate to each other
4. Primary germ layers of the embryo and their relationship to mature tissues
5. How and why tissues are prepared as stained histological sections; the three common planes of section; and some ways that tissues are prepared other than sectioning

5.2 Epithelial Tissue

1. Characteristics that distinguish epithelium from the other three primary tissue classes
2. Functions of the basement membrane and its relationship to an epithelium
3. Defining characteristics of a simple epithelium

STUDY GUIDE

- Four types of simple epithelium and the appearance, functions, and representative locations of each
- Defining characteristics of a stratified epithelium
- Four types of stratified epithelium and the appearance, functions, and representative locations of each
- Distinctions between keratinized and nonkeratinized stratified squamous epithelium, including differences in histology, locations, and functions
- The special protective property and mechanism of urothelium
- Epithelial exfoliation and its clinical relevance

5.3 Connective Tissue

- Characteristics that distinguish connective tissue from the other three primary tissue classes
- Functions of connective tissues
- Cell types found in fibrous connective tissue, and the functions of each
- Fiber types found in fibrous connective tissue, their composition, and the functions of each
- The composition and variations in the ground substance of fibrous connective tissue
- The appearance, functions, and locations of areolar, reticular, dense irregular, and dense regular connective tissue
- The appearance, functions, and locations of adipose tissue, including the differences between white and brown adipose tissue
- Defining characteristics of cartilage as a class; the three types of cartilage and how they differ in histology, function, and location; the relationship of the perichondrium to cartilage; and where perichondrium is absent

- Defining characteristics of osseous tissue as a class; the distinction between spongy and compact bone; and the relationship of the periosteum to bone
- The appearance of cross sections of compact bone
- Why blood is classified as connective tissue; the term for its matrix; and the major categories of formed elements in blood

5.4 Nervous and Muscular Tissues—Excitable Tissues

- Why nervous and muscular tissues are called *excitable tissues* even though excitability is a property of all living cells
- The two basic types of cells in nervous tissue and their functional differences
- The general structure of neurons
- Defining characteristics of muscular tissue as a class
- Three types of muscle and how they differ in histology, function, and location

5.5 Cellular Junctions, Glands, and Membranes

- The general function of cellular junctions
- Differences in the structure and function of tight junctions, desmosomes, hemidesmosomes, and gap junctions
- The definition of a *gland* and the two basic functions of glands
- The developmental, structural, and functional distinctions between exocrine and endocrine glands; examples of each; and why some glands cannot be strictly classified into one category or the other
- Examples of unicellular glands in both the exocrine and endocrine categories
- General histology of a typical exocrine gland

- The scheme for classifying exocrine glands according to the anatomy of their duct systems and their distribution of secretory cells
- Differences between serous, mucous, and mixed glands, and examples of each
- Comparison of the mode of secretion of eccrine, apocrine, and holocrine glands
- The variety of serous, mucous, and other membranes in the body, and names of some specialized membranes of the skin, blood vessels, and joints

5.6 Tissue Growth, Development, Repair, and Degeneration

- Differences between hyperplasia, hypertrophy, and neoplasia as normal and pathological modes of tissue growth
- Differences between differentiation and metaplasia as modes of transformation from one tissue type to another
- What stem cells are and how they relate to developmental plasticity; differences between embryonic and adult stem cells; and differences between totipotent, pluripotent, multipotent, and unipotent stem cells
- Differences between regeneration and fibrosis as modes of tissue repair
- Steps in the healing of a wound such as a cut in the skin
- The general meaning of tissue *atrophy* and two forms or causes of atrophy
- Differences between necrosis and apoptosis as modes of cell death and tissue shrinkage; some normal functions of apoptosis
- Varieties of necrosis including infarction, wet and dry gangrene, and gas gangrene

▶ Testing Your Recall

Answers in Appendix A

- Urothelium is found in
 - the urinary system.
 - the respiratory system.
 - the digestive system.
 - the reproductive system.
 - all of the above.
- The external surface of the stomach is covered by
 - a mucosa.
 - a serosa.
 - the parietal peritoneum.
 - a lamina propria.
 - a basement membrane.
- Which of these is a primary germ layer?
 - epidermis
 - mucosa
 - ectoderm
 - endothelium
 - epithelium
- A seminiferous tubule of the testis is lined with _____ epithelium.
 - simple cuboidal
 - pseudostratified columnar ciliated
 - stratified squamous
 - transitional
 - stratified cuboidal
- _____ prevent fluids from seeping between epithelial cells.
 - Glycosaminoglycans

STUDY GUIDE

- b. Hemidesmosomes
 - c. Tight junctions
 - d. Communicating junctions
 - e. Basement membranes
6. A fixative serves to
 - a. stop tissue decay.
 - b. improve contrast.
 - c. repair a damaged tissue.
 - d. bind epithelial cells together.
 - e. bind cardiomyocytes together.
 7. The collagen of areolar tissue is produced by
 - a. macrophages.
 - b. fibroblasts.
 - c. mast cells.
 - d. leukocytes.
 - e. chondrocytes.
 8. Tendons are composed of _____ connective tissue.
 - a. skeletal
 - b. areolar
 - c. dense irregular
 - d. yellow elastic
 - e. dense regular
 9. The shape of the external ear is due to
 - a. skeletal muscle.
 - b. elastic cartilage.
 - c. fibrocartilage.
 - d. articular cartilage.
 - e. hyaline cartilage.
 10. The most abundant formed element(s) of blood is/are
 - a. plasma.
 - b. erythrocytes.
 - c. platelets.
 - d. leukocytes.
 - e. proteins.
 11. Any form of pathological tissue death is called _____.
 12. The simple squamous epithelium that lines the peritoneal cavity is called _____.
 13. Osteocytes and chondrocytes occupy little cavities called _____.
 14. Muscle cells and axons are often called _____ because of their shape.
 15. Tendons and ligaments are made mainly of the protein _____.
 16. Of the three major categories of muscle, the only one that never has gap junctions is _____.
 17. An epithelium rests on a layer called the _____ between its deepest cells and the underlying connective tissue.
 18. Fibers and ground substance make up the _____ of a connective tissue.
 19. A/An _____ adult stem cell can differentiate into two or more mature cell types.
 20. Any epithelium in which every cell touches the basement membrane is called a/an _____ epithelium.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|-------------|-----------|-------------|
| 1. apo- | 3. ecto- | 7. hyalo- |
| 2. chondro- | 4. -gen | 8. necro- |
| | 5. histo- | 9. plas- |
| | 6. holo- | 10. squamo- |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|--|---|---|
| 1. The esophagus is protected from abrasion by a keratinized stratified squamous epithelium. | 3. Skeletal muscle is defined by the fact that it is always attached to bones. | 7. Tight junctions function primarily to prevent cells from pulling apart. |
| 2. Only the basal cells of a pseudostratified columnar epithelium contact the basement membrane. | 4. The secretions of a gland are produced by the cells of its stroma. | 8. The development of mature tissue types from the immature tissues of a neonate (newborn) is called neoplasia. |
| | 5. In all connective tissues, the matrix occupies more space than the cells do. | 9. Nerve and muscle cells are the body's only electrically excitable cells. |
| | 6. Adipocytes are limited to adipose tissue. | 10. Cartilage is always covered by a fibrous perichondrium. |

STUDY GUIDE

▶ Testing Your Comprehension

1. A woman in labor is often told to push. In doing so, is she consciously contracting her uterus to expel the baby? Justify your answer based on the muscular composition of the uterus.
2. A major tenet of the cell theory is that all bodily structure and function are based on cells. The structural properties of bone, cartilage, and tendons, however, are due more to their extracellular material than to their cells. Is this an exception to the cell theory? Why or why not?
3. When cartilage is compressed, water is squeezed out of it, and when pressure is taken off, water flows back into the matrix. This being the case, why do you think cartilage at weight-bearing joints such as the knees can degenerate from lack of exercise?
4. The epithelium of the respiratory tract is mostly of the pseudostratified columnar ciliated type, but in the alveoli—the tiny air sacs where oxygen and carbon dioxide are exchanged between the blood and inhaled air—the epithelium is simple squamous.
5. Which do you think would heal faster, cartilage or bone? Stratified squamous or simple columnar epithelium? Why?

Explain the functional significance of this histological difference. That is, why don't the alveoli have the same kind of epithelium as the rest of the respiratory tract?

THE INTEGUMENTARY SYSTEM

The shaft of a human hair (SEM). Cells of the hair cuticle, with edges directed upward, are reddish-tan; cells of the follicle adhering to the hair are light tan; and the blue dots are bacteria on the hair.

6.3 Clinical Application: UVA, UVB, and Sunscreens

6.4 Evolutionary Medicine: The Evolution of Skin Color

Module 4: Integumentary System

BRUSHING UP

- The epidermis of the skin is a keratinized stratified squamous epithelium, introduced in table 5.3.
- The dermis is composed of the areolar and dense irregular connective tissues described in tables 5.4 and 5.5. Its main protein is collagen, introduced in section 5.3b.
- The well-known durability of the epidermis depends in part on its desmosomes, depicted in figure 5.28b.
- Reviewing eccrine, apocrine, and holocrine gland types (see fig. 5.32) will help in understanding the types of sweat glands and oil glands of the skin in this chapter.
- Several issues in this chapter, from sweat glands to hair to skin color, are based on the principles of human evolution and natural selection explained in section 1.4.

We pay more daily attention to our skin, hair, and nails than to any other organ system. It is, after all, the most visible one, and its appearance strongly affects our social interactions. Few people venture out of the house without first looking in a mirror to see if their skin and hair are presentable. Social considerations aside, the integumentary system is important to one's self-image, and a positive self-image is important to the attitudes that promote overall good health. Care of the integumentary system is thus a particularly important part of the total plan of patient care.

Dermatology¹ is the branch of medicine specializing in the care and treatment of the skin. Even a general physical examination, however, should include inspection of the skin, hair, and nails. Their appearance can provide clues not only to their own health, but also to deeper disorders such as liver cancer, anemia, and heart failure. The skin also is the most vulnerable of our organs, exposed to radiation, trauma, infection, and injurious chemicals. Consequently, it needs and receives more medical attention than any other organ system.

6.1 Skin and Subcutaneous Tissue

Expected Learning Outcomes

When you have completed this section, you should be able to

- list the functions of the skin and relate them to its structure;
- describe the histological structure of the epidermis, dermis, and subcutaneous tissue;
- describe the normal and pathological colors that the skin can have, and explain their causes; and
- describe the common markings of the skin.

The **integumentary**² system consists of the skin, hair, nails, and their associated glands. The **skin (integument)** is the body's largest and heaviest organ. In adults, it covers an area of 1.5 to 2.0 m² and accounts for about 8% of the body weight. It consists of two layers: a stratified squamous epithelium called the *epidermis* and a deeper connective tissue layer called the *dermis* (**fig. 6.1**). Below the dermis is another connective tissue layer, the *hypodermis*, which isn't part of the skin but is customarily studied in conjunction with it.

Most of the skin is 1 to 2 mm thick, but it ranges from less than 0.5 mm on the eyelids to 6 mm between the shoulder blades. The difference is due mainly to variation in thickness of the dermis, although skin is classified as thick or thin based on the relative thickness of the epidermis alone. **Thick skin** covers the palms, soles, and corresponding surfaces of the fingers and toes. Its epidermis alone is about 0.5 mm thick, due to a very thick surface layer of dead cells called the *stratum corneum* (see fig. 6.3). Thick skin has sweat glands but no hair follicles or sebaceous (oil) glands. The rest of the body is covered with **thin skin**, which has an epidermis about 0.1 mm thick, with a thin stratum corneum (see fig. 6.6). It possesses hair follicles, sebaceous glands, and sweat glands.

6.1a Functions of the Skin

The skin is much more than a container for the body. It has a variety of important functions that go well beyond appearance.

1. **Resistance to trauma and infection.** The skin suffers the most physical injuries to the body, but it resists and recovers from trauma better than other organs do. The epidermal cells are packed with the tough protein **keratin** and linked by strong desmosomes that give this epithelium its durability. Few infectious organisms can penetrate the intact skin. Bacteria and fungi colonize the surface, but their numbers are kept in check by its relative dryness, its slight acidity (pH 4–6), and defensive antimicrobial peptides called *dermcidin* and *defensins*. The protective acidic film is called the *acid mantle*.
2. **Other barrier functions.** The skin is important as a barrier to water. It prevents the body from absorbing excess water when you're swimming or bathing, but even more importantly, it prevents the body from losing excess water. The epidermis is also a barrier to ultraviolet (UV) rays, blocking much of this cancer-causing radiation from reaching deeper tissue layers, and it is a barrier to many potentially harmful chemicals. It is, however, permeable to several drugs and poisons (see Deeper Insight 6.1).
3. **Vitamin D synthesis.** The skin carries out the first step in the synthesis of vitamin D, which is needed for bone development and maintenance. The liver and kidneys complete the process. This is further detailed in figure 7.16.
4. **Sensation.** The skin is our most extensive sense organ. It is equipped with a variety of nerve endings that react to heat,

¹dermat = skin; logy = study of

²integument = covering

FIGURE 6.1 Structure of the Skin and Subcutaneous Tissue. The epidermis is peeled up at the upper left corner to show the dermal–epidermal boundary.

cold, touch, texture, pressure, vibration, and tissue injury. These sensory receptors are especially abundant on the face, palms, fingers, soles, nipples, and genitals. There are relatively few on the back and in skin overlying joints such as the knees and elbows.

DEEPER INSIGHT 6.1

CLINICAL APPLICATION

Transdermal Absorption

The ability of the skin to absorb chemicals makes it possible to administer several medicines as ointments or lotions, or by means of adhesive patches that release the medicine steadily through a membrane. For example, inflammation can be treated with a hydrocortisone ointment, nitroglycerine patches are used to relieve heart pain, nicotine patches are used to help overcome tobacco addiction, and other medicated patches are used to control high blood pressure and motion sickness.

Unfortunately, the skin can also be a route for absorption of poisons. These include pesticides; toxins from poison ivy and other plants; metals such as mercury, arsenic, and lead; and solvents such as acetone (nail polish remover) and paint thinner. Some of these can cause brain damage, liver failure, or kidney failure, which is good reason for using protective gloves when handling such substances.

5. **Thermoregulation.** The skin receives 10 times as much blood flow as it needs for its own maintenance, and is richly supplied with nerve endings called thermoreceptors, which monitor the body surface temperature. All of this relates to its great importance in regulating body temperature. In response to chilling, the body retains heat by constricting blood vessels of the dermis (*cutaneous vasoconstriction*), keeping warm blood deeper in the body. In response to overheating, it loses excess heat by dilating those vessels (*cutaneous vasodilation*), allowing more blood to flow close to the surface and lose heat through the skin. If this is insufficient to restore normal temperature, sweat glands secrete perspiration. The evaporation of sweat can have a powerful cooling effect. Thus, the skin plays roles in both warming and cooling the body.

6. **Nonverbal communication.** The skin is an important means of nonverbal communication. Humans, like most other primates, have much more expressive faces than other mammals (**fig. 6.2**). Complex skeletal muscles insert in the dermis and pull on the skin to create subtle and varied facial expressions. The general appearance of the skin, hair, and nails—whether the ravages of adolescent acne, the presence of a birthmark or scar, or just a “bad hair day”—is also important to social acceptance and to a person’s self-image and emotional state.

(a)

(b)

FIGURE 6.2 Importance of the Skin in Nonverbal Expression. (a) Primates such as humans and this chimpanzee differ from other mammals in having very expressive faces due to facial muscles that insert on the collagen fibers of the dermis and move the skin. (b) Human facial expression, reflecting the actions of complex facial muscles surveyed in chapter 10.

a: DLILLC/Corbis/VCG/Getty Images; b: Joe DeGrandis/Ken Saladin

6.1b The Epidermis

The **epidermis**³ is a keratinized stratified squamous epithelium, as described in table 5.3. That is, its surface consists of dead cells packed with the tough protein keratin. Like other epithelia, the epidermis lacks blood vessels and depends on the diffusion of nutrients from the underlying connective tissue. It has sparse nerve endings for touch and pain, but most sensations of the skin are due to nerve endings in the dermis.

Cells of the Epidermis

The epidermis is composed of five types of cells (fig. 6.3):

1. **Keratinocytes** (keh-RAT-ih-no-sites) are the great majority of epidermal cells. They are named for their role in synthesizing keratin. In ordinary histological specimens, nearly all visible epidermal cells are keratinocytes.
2. **Stem cells** are undifferentiated cells that divide and give rise to the keratinocytes. They are found only in the deepest layer of the epidermis, called the *stratum basale*.
3. **Melanocytes** also occur only in the stratum basale, amid the stem cells and deepest keratinocytes. They synthesize varieties of the pigment *melanin*, described later. They have branching processes that spread among the keratinocytes and continually shed melanin-containing fragments (*melanosomes*) from their tips. The keratinocytes phagocytize these and gather the melanin granules on the “sunny side” of their nucleus. Like a parasol, the dark granules shield the DNA from ultraviolet rays.
4. **Tactile cells**, relatively few in number, are receptors for touch. They, too, are found in the basal layer of the epidermis and are associated with an underlying dermal nerve fiber. The tactile cell and its nerve fiber are collectively called a *tactile disc*.

5. **Dendritic**⁴ cells are found in two layers of the epidermis called the *stratum spinosum* and *stratum granulosum* (described in the next section). They are immune cells that originate in the bone marrow but migrate to the epidermis and epithelia of the oral cavity, esophagus, and vagina. The epidermis has as many as 1,800 dendritic cells per square millimeter. They stand guard against toxins, microbes, and other pathogens that penetrate into the skin. When they detect such invaders, they alert the immune system so the body can defend itself.

Layers of the Epidermis

Cells of the epidermis are arranged in four to five zones, or strata (five in thick skin) (fig. 6.3). The following description progresses from deep to superficial, and from the youngest to the oldest keratinocytes.

1. The **stratum basale** (bah-SAY-lee) consists mainly of a single layer of cuboidal to low columnar keratinocytes resting on the basement membrane. Scattered among these are the melanocytes, tactile cells, and stem cells. As stem cells divide, they give rise to keratinocytes that migrate toward the surface and replace lost epidermal cells.
2. The **stratum spinosum** (spy-NO-sum) consists of several layers of keratinocytes. In most places, this is the thickest stratum, but on the palms and soles it is usually exceeded by the stratum corneum. The deepest cells of the stratum spinosum continue dividing, but as they’re pushed farther upward, they cease. Instead, they produce more and more keratin filaments, which cause the cells to flatten. Therefore, the higher up you look in the stratum spinosum, the flatter the cells appear. Dendritic cells are also found throughout the stratum spinosum, but aren’t usually identifiable in routinely stained tissue sections.

³epi = above, upon; derm = skin

⁴dendr = tree, branch

FIGURE 6.3 Layers and Cell Types of the Epidermis. (a) Photo. (b) Drawing with added features of skin not visible in the photo. Gaps between the keratinocytes are an artifact created by cell shrinkage during fixation, but are typically seen in microscope slides of skin. The drawing accentuates the ladderlike tight junctions that bridge these gaps. **APR**

a: Biophoto Associates/Science Source

The stratum spinosum is named for an artificial appearance (*artifact*) created by the histological fixation of skin specimens. Keratinocytes are firmly attached to each other by numerous desmosomes, which partly account for the toughness of the epidermis. Histological fixatives shrink the keratinocytes so they pull away from each other, but they remain attached by the desmosomes—like two people holding hands while they step farther apart. The desmosomes thus create bridges from cell to cell, giving each cell a spiny appearance from which we derive the word *spinosum*. Keratinocytes are also bound to each other by tight junctions, which make an essential contribution to water retention by the skin.

3. The **stratum granulosum** consists of three to five layers of flat keratinocytes—more in thick skin than in thin skin. The keratinocytes of this layer contain coarse, dark-staining *keratohyalin granules* that give the layer its name.
4. The **stratum lucidum**⁵ (LOO-sih-dum) is a thin zone superficial to the stratum granulosum, seen only in thick skin.

Here, the keratinocytes are densely packed with a clear protein named *eleidin* (ee-LEE-ih-din). The cells have no nuclei or other organelles. This zone has a pale, featureless appearance with indistinct cell boundaries.

5. The **stratum corneum** consists of up to 30 layers of dead, scaly, keratinized cells that form a durable surface layer. It is especially resistant to abrasion, penetration, and water loss.

The Life History of a Keratinocyte

Dead cells constantly flake off the skin surface. Because we constantly lose these cells, we must continually replace them. Keratinocytes are produced deep in the epidermis by the mitosis of stem cells in the stratum basale. Some of the deepest keratinocytes in the stratum spinosum also continue dividing. Mitosis requires an abundant supply of oxygen and nutrients, which these deep cells acquire from the blood vessels in the nearby dermis. Once the epidermal cells migrate more than two or three cells away from the dermis, their mitosis ceases. Mitosis is seldom seen in prepared slides of the skin, because it occurs mainly at night and most tissue specimens are taken during the day.

⁵stratum = layer; lucid = light, clear

As new keratinocytes form, they push the older ones toward the surface. In 30 to 40 days, a keratinocyte makes its way to the surface and flakes off. This migration is slower in old age and faster in skin that has been injured or stressed. Injured epidermis regenerates more rapidly than any other tissue in the body. Mechanical stress from manual labor or tight shoes accelerates keratinocyte multiplication and results in *calluses* or *corns*, thick accumulations of dead keratinocytes on the hands or feet.

As keratinocytes are shoved upward by the dividing cells below, they flatten and produce more keratin filaments and lipid-filled **lamellar granules**. In the stratum granulosum, four important developments occur: (1) Keratohyalin granules release a protein called *filaggrin* that binds the cytoskeletal keratin filaments together into coarse, tough bundles. (2) The cells produce a tough layer of *envelope proteins* just beneath the plasma membrane, resulting in a nearly indestructible protein sac around the keratin bundles. (3) Lamellar granules release a lipid mixture that spreads out over the cell surface and waterproofs it. (4) Finally, as these barriers cut the keratinocytes off from the supply of nutrients from below, their organelles degenerate and the cells die, leaving just the tough waterproof sac enclosing coarse bundles of keratin. These processes, along with the tight junctions between keratinocytes, result in an **epidermal water barrier** that is crucial to the retention of body water.

The stratum corneum consists of compact layers of dead keratinocytes and keratinocyte fragments. The dead cells soon **exfoliate** (flake off) from the epidermal surface as specks called **dander**. Dander floats around as tiny white specks in the air, settles on household surfaces, and forms much of the house dust that accumulates there. *Dandruff* is composed of clumps of dander stuck together by sebum (oil).

6.1c The Dermis

Beneath the epidermis is a connective tissue layer, the **dermis**. It ranges from 0.2 mm thick in the eyelids to about 4 mm thick in the palms and soles. It is composed mainly of collagen, but also contains

elastic and reticular fibers, fibroblasts, and the other cells typical of fibrous connective tissue. It is well supplied with blood vessels, cutaneous glands, and nerve endings. The hair follicles and nail roots are embedded in the dermis. In the face, skeletal muscles attach to dermal collagen fibers and produce such expressions as a smile, a wrinkle of the forehead, or the lifting of an eyebrow (see fig. 6.2).

The boundary between the epidermis and dermis is histologically conspicuous and usually wavy. The upward waves are fingerlike extensions of the dermis called **dermal papillae**⁶ (see fig. 6.3), and the downward epidermal waves between the papillae are called **epidermal ridges**. The dermal and epidermal boundaries thus interlock like corrugated cardboard, an arrangement that resists slippage of the epidermis across the dermis. If you look closely at your hand and wrist, you will see delicate furrows that divide the skin into tiny rectangular to rhomboidal areas. The dermal papillae produce the raised areas between the furrows. On the fingertips, this wavy boundary forms the *friction ridges* that produce fingerprints. In highly sensitive areas such as the lips and genitals, exceptionally tall dermal papillae allow blood capillaries and nerve fibers to reach close to the surface. This imparts a redder color and more sensitivity to touch in such areas.

▶▶▶ APPLY WHAT YOU KNOW

Dermal papillae are relatively high and numerous in palmar and plantar skin but low and few in number in the skin of the face and abdomen. What do you think is the functional significance of this difference?

There are two zones of dermis called the papillary and reticular layers (**fig. 6.4**). The **papillary layer** (PAP-ih-lerr-ee) is a thin zone of areolar tissue in and near the dermal papillae. This loosely organized tissue allows for mobility of leukocytes and other defenses against organisms introduced through breaks in the epidermis. This layer is especially rich in small blood vessels.

⁶pap = nipple; illa = little

FIGURE 6.4 Layers of the Dermis. (a) Light micrograph (LM) of axillary skin, with the epidermis stained pink and dermal collagen stained blue. (b) The papillary layer, composed of loosely organized, random-seeming bundles of collagen fibers; open fluid-filled space; and numerous small blood vessels that nourish both dermis and epidermis. (c) The reticular layer, composed of coarser, tougher bundles of collagen and less open space. Parts (b) and (c) are scanning electron micrographs (SEMs).

a: Dennis Strete/McGraw Hill; b: David M. Phillips/Science Source; c: Susumu Nishinaga/Science Source

The **reticular**⁷ layer of the dermis is deeper and much thicker. It consists of dense irregular connective tissue; it is much more fibrous than cellular, and thus tougher than the papillary layer. The boundary between the papillary and reticular layers is often vague. In the reticular layer, the collagen forms thicker bundles with less room for ground substance, and there are often small clusters of adipocytes. Stretching of the skin in obesity and pregnancy can tear the collagen fibers and produce *striae* (STRY-ee), or stretch marks. These occur especially in areas most stretched by weight gain: the thighs, buttocks, abdomen, and breasts.

There are extensive plexuses of blood vessels at the dermal–epidermal boundary, in mid-dermis, and between the dermis and hypodermis. When dermal blood vessels are damaged by such causes as burns and friction from tight shoes, serous fluid can seep out of the vessels and accumulate as a **blister**, separating the epidermis from the dermis until the fluid is either reabsorbed or expelled by rupture of the blister.

6.1d The Hypodermis

Beneath the skin is a layer called the **hypodermis**⁸ or **subcutaneous tissue** (see fig. 6.1). The boundary between the dermis and hypodermis is indistinct, but the hypodermis generally has more areolar and adipose tissue. It pads the body and binds the skin to the underlying tissues. Drugs are introduced into the hypodermis

by injection because the subcutaneous tissue is highly vascular and absorbs them quickly.

Subcutaneous fat is hypodermis composed predominantly of adipose tissue. It serves as an energy reservoir and thermal insulation, and it is compressible and protects deeper tissue by absorbing pressure and blows to the body. It's not uniformly distributed; for example, it is virtually absent from most of the scalp but relatively abundant in the abdomen, hips, thighs, and female breasts. The subcutaneous fat averages about 8% thicker in women than in men, and varies with age. Infants and elderly people have less subcutaneous fat than other people and are therefore more sensitive to cold.

Table 6.1 summarizes the layers of the skin and hypodermis, from superficial to deep.

6.1e Skin Color

Variations in skin and hair color arise mainly from varieties and amounts of **melanin**. The two classes of integumentary melanin are dark **eumelanin**¹⁰ and lighter, reddish–yellow **pheomelanin**.¹¹ Eumelanin has two varieties called **brown** and **black eumelanin**. These underlie the colors of tan, brown, and black skin, including the effect of suntanning. Pheomelanin, which gets its color from a higher sulfur content, imparts the yellowish to reddish tones of some Asian and Native American complexions and the pinkish tones of white skin. (See chapter 16 on the role of these pigments in eye

DEEPER INSIGHT 6.2

CLINICAL APPLICATION

Skin Grafts

Burns are among the most common and serious injuries to the skin (see section 6.4b). The skin recovers from most burns on its own by proliferation of adjacent undamaged tissue. Third-degree burns, however, destroy the full thickness of the epidermis and dermis and require **skin grafts** to restore appearance and function as much as possible.

The ideal graft is an **autograft**,⁹ using epidermis and part of the dermis harvested from elsewhere on the same patient's body—taking skin from the thigh, for example, to repair a facial burn, but leaving behind some dermis to regenerate the harvested skin. The advantage of an autograft is that it isn't rejected by the immune system. Relatively small areas of healthy skin can be made to cover much larger lesions by means of **meshed skin grafts**. The harvested skin is cut with an instrument into a mesh pattern and stretched over the lesion (**fig. 6.5**). Regenerating cells fill in the gaps in the mesh.

The next-best method, if the burns are too extensive for autografting, is to use skin from an identical twin to avoid immune rejection. Since identical twins are rare, however, the best one can usually hope for is another close relative as donor. An **allograft** is skin from any other person, usually from deceased donors. Because of immune rejection, these usually serve only as temporary coverings, serving until the patient is well enough to donate skin for a replacement autograft. A major field of contemporary tissue engineering is the design and production of tissue-cultured cellular alternatives to donor skin, as well

FIGURE 6.5 A Meshed Skin Graft.

Barry Slaven/Science Source

as artificial membranes for temporary or permanent replacement of destroyed skin. Hybrid approaches use cells cultured from a small skin biopsy and seeded onto synthetic membranes.

⁷reti = network; cul = little

⁸hypo = below; derm = skin

⁹auto = self

¹⁰eu = true; melan = black, dark; in = substance

¹¹pheo = dusky; melan = black, dark; in = substance

TABLE 6.1 Stratification of the Skin and Hypodermis

Layer	Description
Epidermis	Keratinized stratified squamous epithelium
Stratum corneum	Dead, keratinized cells of the skin surface
Stratum lucidum	Clear, featureless, narrow zone seen only in thick skin
Stratum granulosum	Two to five layers of cells with dark-staining keratohyalin granules; scanty in thin skin
Stratum spinosum	Many layers of keratinocytes, typically shrunken in fixed tissues but attached to each other by desmosomes, which give them a spiny look; progressively flattened the farther they are from the dermis. Dendritic cells are abundant here but are not distinguishable in routinely stained preparations.
Stratum basale	Single layer of cuboidal to columnar cells resting on basement membrane; site of most mitosis; consists of stem cells, keratinocytes, melanocytes, and tactile cells, but these are difficult to distinguish with routine stains. Melanin is conspicuous in keratinocytes of this layer in black to brown skin.
Dermis	Fibrous connective tissue, richly endowed with blood vessels and nerve endings. Sweat glands and hair follicles originate here and in hypodermis.
Papillary layer	Superficial one-fifth of dermis; composed of areolar tissue; often extends upward as dermal papillae
Reticular layer	Deeper four-fifths of dermis; dense irregular connective tissue
Hypodermis	Areolar or adipose tissue between skin and muscle

color.) Other contributing factors in skin color are various degrees of show-through of dermal blood vessels and white collagen. The skin is redder in places where blood vessels come closest to the surface, such as the lips, parts of the genitals, and nipples of light-skinned people. Some authorities maintain, and others dispute, that the **carotene**¹² pigments of yellow and orange vegetables can accumulate in the stratum corneum, dermis, and subcutaneous fat and contribute to skin colors of those tints. This may be why the thickened skin of the heel and calluses of the feet often appear yellowish.

As described earlier, melanin is synthesized by epidermal melanocytes of the stratum basale, but they pass it off to the keratinocytes, which accumulate it. Most of it is in the stratum basale, but it extends throughout the epidermal strata in dark complexions (**fig. 6.6a**). People of different colors have essentially the same number of melanocytes, but in dark skin, the melanocytes produce greater quantities of pigment in greater amounts, the melanin granules in the keratinocytes are quite spread out, and the melanin breaks down more slowly. In light skin, the melanin is less abundant and is clumped near the keratinocyte nucleus, so it imparts less color. It also breaks down more rapidly, so little of it is seen beyond the stratum basale, if even there (**fig. 6.6b**).

Skin color also varies with exposure to the ultraviolet rays of sunlight, which stimulate melanin synthesis and darken the skin. A suntan fades as melanin is degraded in older keratinocytes and as keratinocytes migrate to the surface and exfoliate. The amount of melanin also varies from place to place on the body. It is relatively concentrated in freckles and moles, on the dorsal surfaces of the hands and feet as compared with the palms and soles, on the nipple and surrounding area (areola) of the breast, around the anus, on the scrotum and penis, and on the lateral surfaces of the female genital folds (labia majora).

Deeper Insight 6.4 describes the evolution of skin color and explains the main reasons for human variation in this trait.

The skin may also exhibit abnormal colors of diagnostic value:

- **Cyanosis**¹³ is a blue or gray hue of the skin and mucous membranes resulting from a deficiency of oxygen in the circulating blood. Oxygen deficiency turns the hemoglobin a reddish violet color, which is lightened to blue-violet as it shows through the white dermal collagen. It is most visible in areas such as the lips and oral mucosa, including the tongue, with an abundance of blood capillaries and a thin overlying epithelium. It may also be seen in the palms and under the fingernails, but is harder to see here in persons with brown or black skin. Oxygen deficiency can result from conditions that prevent the blood from picking up a normal load of oxygen in the lungs, such as airway obstructions in drowning and choking, lung diseases such as emphysema, and respiratory arrest. Cyanosis also occurs in situations such as cold weather and cardiac arrest, when blood flows so slowly through the skin that the tissues consume its oxygen faster than freshly oxygenated blood arrives.
- **Erythema**¹⁴ (ERR-ih-THEE-muh) is abnormal redness of the skin. It is a common sign of infection and inflammation, but erythema of shorter duration occurs in such situations as exercise, hot weather, sunburn, anger, and embarrassment. Erythema results from increased blood flow in dilated cutaneous blood vessels or by dermal pooling of red blood cells that have escaped from abnormally permeable capillaries, as in sunburn. It may be narrowly circumscribed, as in the red area around a mosquito or tick bite, or spread more broadly

¹²carot = carrot

across the skin. In those with more melanized skin, it may have a more burgundy color.

- **Pallor** is a pale or ashen color that occurs when there is so little blood flow through the skin, or the blood oxygen level is so low, that the white of the dermal collagen shows through. It is often first noticed in the face; paleness of the palms is also a common sign. On brown skin, it may show as unusual lightness of the normally dark palmar creases. Pulling the lower eyelid down may show its inner mucosa to be much lighter than its usual red-pink color. Pallor can result from emotional stress, low blood pressure, circulatory shock, cold temperatures, or severe anemia.
- **Albinism**¹⁵ (fig. 6.7a) is a genetic lack of melanin that usually results in milky white hair and skin, and blue-gray eyes. Melanin is synthesized from the amino acid tyrosine by the enzyme tyrosinase. People with albinism have inherited a recessive, nonfunctional tyrosinase allele from both parents.
- **Jaundice**¹⁶ (fig. 6.7b) is yellowing of the skin and whites of the eyes resulting from high levels of bilirubin in the blood. The effect on skin color may be subtle and overlooked in persons with brown or black skin, but the discoloration of the eyes is unmistakable in anyone. Bilirubin is a hemoglobin breakdown product. When erythrocytes get old, they disintegrate and release their hemoglobin. The liver and spleen convert hemoglobin to bilirubin, which the liver excretes in the bile. Bilirubin can accumulate enough to dis-

color the skin, however, in such situations as a rapid rate of erythrocyte destruction; when diseases such as cancer, hepatitis, and cirrhosis compromise liver function; and in premature infants, where the liver is not well enough developed to dispose of bilirubin efficiently.

- A **hematoma**,¹⁷ or bruise, is a mass of clotted blood showing through the skin. It is usually due to accidental trauma (blows to the skin), but it may indicate hemophilia, other metabolic or nutritional disorders, or physical abuse.

▶▶▶ APPLY WHAT YOU KNOW

An infant brought to a clinic shows abnormally yellow skin. What sign could you look for to help decide whether this was due to jaundice or to a large amount of carotene from strained vegetables in the diet?

6.1f Skin Markings

The skin is marked by many lines, creases, ridges, and patches of accentuated pigmentation. **Friction ridges** are the markings on the fingertips that leave distinctive oily fingerprints on surfaces we touch. They are characteristic of most primates, though their function has long been obscure. When we stroke an uneven surface, friction ridges enhance fingertip sensitivity to texture by vibrating and stimulating sense organs called *lamellar corpuscles* deeper in the skin. They also improve one's grasp and aid in the manipulation

¹⁵*alb* = white; *ism* = state, condition

¹⁶*jaun* = yellow

¹⁷*hemat* = blood; *oma* = mass

(a)

(b)

of small and rough-surfaced objects. Friction ridges form during fetal development and remain essentially unchanged for life. Their patterns result from a combination of heredity and the surfaces that the fetus randomly touches with its fingertips before birth. Thus, everyone has a unique pattern of friction ridges; not even identical twins produce identical fingerprints.

Many wonder why our fingertips and toes wrinkle like prunes when they've been in water for several minutes. The effect was long attributed to passive absorption of water and swelling of the skin, but this fails to account for some long-known facts of the matter. The "prune fingers" don't occur if the sympathetic nerves to the fingertips have been severed or they're blocked by drugs. The phenomenon also occurs nowhere but the fingertips and feet, so it's not a property of skin in general. The wrinkling seems to result from the constriction of dermal blood vessels in the fingertip pads, and can be produced also by chemicals that directly stimulate vessel constriction. It has been hypothesized that the prune texture acts like the tread of a car's tires on a wet road, squeezing water away from a surface as a hand grasps it (or a foot, too, as in monkeys walking on tree limbs). This would enable us to get a better grip on wet objects or walk with less slipping on rocks along a shore, and lessen the chance of other primates slipping, perhaps fatally, from wet branches in the forest canopy.

Flexion lines (flexion creases) are the lines on the flexor surfaces of the digits, palms, wrists, elbows, and other places (see atlas B, fig. B.19). They mark sites where the skin folds during flexion of the joints. The skin is tightly bound to deeper connective tissues along these lines.

Freckles and moles are tan to black aggregations of melanized keratinocytes. **Freckles** are flat patches that vary with heredity and exposure to the sun. A **mole (nevus)** is an elevated patch of melanized skin, often with hair. Moles are harmless and sometimes even regarded as "beauty marks," but they should be watched for changes in color, diameter, or contour that may suggest malignancy (skin cancer) (see section 6.4a).

Birthmarks, or **hemangiomas**,¹⁸ are patches of skin discolored by benign tumors of the blood capillaries. *Capillary hemangiomas* (strawberry birthmarks) usually develop about a month after birth. They become bright red to deep purple and develop small capillary-dense elevations that give them a strawberry-like appearance. About 90% of capillary hemangiomas disappear by the age of 5 or 6 years. *Cavernous hemangiomas* are flatter and duller in color. They are present at birth, enlarge up to 1 year of age, and then regress. About 90% disappear by the age of 9 years. A *port-wine stain* is flat and pinkish to dark purple in color. It can be quite large and remains for life.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. What is the major histological difference between thick and thin skin? Where on the body is each type of skin found?
2. How does the skin help to adjust body temperature?
3. List the five cell types of the epidermis. Describe their locations and functions.
4. List the five layers of epidermis from deep to superficial. What are the distinctive features of each layer? Which layer is often absent?
5. What are the two layers of the dermis? What type of tissue composes each layer?
6. Name the pigments responsible for normal skin colors and explain how certain conditions can produce discolorations of the skin.

¹⁸hem = blood; angi = vessels; oma = mass, tumor

FIGURE 6.8 Structure of a Hair and Its Follicle. (a) Anatomy of the follicle and associated structures. (b) Light micrograph of the base of a hair follicle.

b: Ed Reschke/Stone/Getty Images

6.2 Hair and Nails

Expected Learning Outcomes

When you have completed this section, you should be able to

- distinguish between three types of hair;
- describe the histology of a hair and its follicle;
- discuss some theories of the purposes served by various kinds of hair; and
- describe the structure and function of nails.

The hair, nails, and cutaneous glands are the **accessory organs (appendages)** of the skin. Hair and nails are composed mostly of dead, keratinized cells. The stratum corneum of the skin is made of pliable **soft keratin**, but the hair and nails are composed mostly of **hard keratin**. This is more compact than soft keratin and is toughened by numerous disulfide bridges between the keratin molecules.

6.2a Hair

A hair is also known as a **pilus** (PY-lus); in the plural, **pili** (PY-lye). It is a slender filament of keratinized cells that grows from an oblique tube in the skin called a **hair follicle** (fig. 6.8).

Distribution and Types

Hair occurs almost everywhere on the body except palms and soles; palmar, plantar, and lateral surfaces and distal segments of the fingers and toes; and the lips, nipples, and parts of the genitals. The limbs and trunk have about 55 to 70 hairs per square centimeter, and the face has about 10 times as many. There are about 30,000 hairs in a man's beard and about 100,000 hairs in the average person's scalp. The density of hair doesn't differ much from one person to another or even between the sexes; indeed, it is virtually the same in humans, chimpanzees, and gorillas. Differences in apparent hairiness are due mainly to differences in texture and pigmentation.

Not all hair is alike, even on one person. Over the course of our lives, we grow three kinds of hair: downy, vellus, and terminal hair. **Downy hair (lanugo¹⁹)** is fine, unpigmented hair that appears on the fetus in the last 3 months of development. By the time of birth, most of it is replaced by similar fine, pale hair called **vellus hair**.²⁰ Vellus hair constitutes about two-thirds of the hair of women, one-tenth of the hair of men, and all the hair of children except for the eyebrows, eyelashes, and hair of the scalp. **Terminal hair** is longer, coarser, and usually more heavily

¹⁹lan = down, wool

²⁰vellus = fleece

pigmented. It forms the eyebrows and eyelashes and covers the scalp; after puberty, it also forms the axillary and pubic hair, all facial hair, and some of the hair on the trunk and limbs.

Hairs range from about 17 to 180 μm in diameter; this varies with genetics, ancestry, age, and locations on the body, and it changes with weather. The greatest diameters are in *guard hairs* of the eyelashes, eyebrows, and nostrils. People of Asian ancestry have thicker hairs than those of White European ancestry, and those of Black African ancestry thicker still.

Structure of the Hair and Follicle

The portion of a hair above the skin is called the **shaft**, and all that beneath the surface is the **root**. The root penetrates deeply into the dermis or hypodermis and ends with a dilation called the **bulb**. The only living cells of a hair are in and near the bulb. The bulb grows around a bud of vascular connective tissue called the **dermal papilla**, which provides the hair with its sole source of nutrition. Immediately above the papilla is a region of mitotically active cells, the **hair matrix**, which is the hair's growth center. All cells higher up are dead.

In cross section, a hair reveals up to three layers. From the inside out, these are the medulla, cortex, and cuticle. The **medulla** is a core of loosely arranged cells and air spaces. It is most prominent in thick hairs such as those of the eyebrows, but narrower in hairs of medium thickness and absent from the thinnest hairs of the scalp and elsewhere. The **cortex** constitutes most of the bulk of a hair. It consists of several layers of elongated keratinized cells that appear cuboidal to flattened in cross sections. The **cuticle** is composed of multiple layers of thin, scaly cells that overlap each other like roof shingles with their free edges directed upward (see this chapter's opening photo). Cells lining the follicle are like shingles facing in the opposite direction. They interlock with the scales of the hair cuticle and resist pulling on the hair. When a hair is pulled out, some follicle cells of this layer come with it. The scaly cuticle also helps keep the hairs separated so they don't become matted together.

The follicle is a diagonal tube that contains the hair root. It has two principal layers: an **epithelial root sheath** and a **connective tissue root sheath**. The epithelial root sheath is an extension of the epidermis; it consists of stratified squamous epithelium and lies immediately adjacent to the hair root. Toward the deep end of the follicle, it widens to form a **bulge**, a source of stem cells for follicle growth. The connective tissue root sheath, which is derived from the dermis and composed of collagenous connective tissue, surrounds the epithelial sheath and is somewhat denser than the adjacent dermis.

Associated with the follicle are nerve and muscle fibers. Nerve fibers called **hair receptors** entwine each follicle and respond to hair movements. You can feel their effect by carefully moving a single hair with a pin or by lightly running your finger over the hairs of your forearm without touching the skin. Each hair has an **arrector muscle**, a bundle of smooth muscle cells extending from dermal collagen fibers to the connective tissue root sheath of the follicle (see figs. 6.1 and 6.8a). In response to cold, fear, touch, or other stimuli, the sympathetic nervous system stimulates the arrector muscle to contract, making the hair stand on end and wrinkling the skin in such areas as the scrotum and areola. This response is called

piloerection.²¹ In other mammals, it traps an insulating layer of warm air next to the skin or makes the animal appear larger and less vulnerable to a potential enemy. In humans, it pulls the follicles into a vertical position and causes "goose bumps," but serves no useful purpose.

Hair Texture and Color

Hair color is due to pigment granules in cells of the cortex. It is up to 97% genetic, but doesn't follow any simple or predictable pattern of heredity from parental hair colors. It is controlled by at least 124 gene loci—some coding directly for melanin-synthesizing enzymes, whereas other genes affect the motility, survival, and gene expression of the pigment-producing cells. This is a good example of the polygenic inheritance explained in chapter 4 (section 4.4d). Black and brown hair result from various ratios of black and brown eumelanin. Blond hair has no black eumelanin and only a small amount of brown eumelanin. Red hair results from a combination of brown eumelanin and pheomelanin. Gray and white hair result from a scarcity of melanin and the presence of air in the medulla. Hair color changes with age, especially from childhood to adulthood and then graying in older age. The texture of hair is related to differences in cross-sectional shape (**fig. 6.9**)—straight hair is round, wavy hair is oval, and tightly curled hair is relatively flat (ribbonlike).

Hair Growth and Loss

Each hair follicle goes through three developmental phases called the **hair cycle**. At any given time, about 90% of the scalp follicles are in a growth stage called **anagen**.²² Stem cells in the hair bulge multiply, the follicle deepens, and the hair grows in length during this time. Anagen lasts about 6 to 8 years for any given follicle. This is followed by **catagen**,²³ in which mitosis ceases, the follicle shrinks, and the hair dies and loses its anchorage. The hair becomes a **club hair**, named for a hard keratinized knot at its base. Club hairs are easily pulled out by brushing the hair, and the hard club can be felt at the end. Catagen lasts for about 2 to 3 weeks, then is followed by a **telogen**²⁴ stage, in which the follicle rests for 1 to 3 months. It then begins the process anew, starting over with anagen and the growth of a new hair, often alongside the old club hair. We lose 50 to 100 scalp hairs daily, but fortunately, the follicles are asynchronous, so we don't lose all our hairs at once.

Scalp hairs grow fastest from adolescence until the 40s, at a rate of about 1 mm per 3 days (10–18 cm/year). After that, an increasing percentage of follicles are in the catagen and telogen phases rather than the growing anagen phase. Follicles also shrink and begin producing wispy vellus hairs instead of thicker terminal hairs. Thinning of the hair, or baldness, is called **alopecia**²⁵ (AL-oh-PEE-she-uh). It occurs to some degree in both sexes and may be worsened by disease, poor nutrition, fever, emotional stress, radiation, or chemotherapy. In the great majority of cases, however, it is simply a matter of aging.

²¹pilo = hair

²²ana = up; gen = build, produce

²⁵alopecia = fox mange

FIGURE 6.9 The Basis of Hair Color and Texture. Note the round cross-sectional shape of straight hair (a, b) compared to the flatter shape of wavy hair (c, d). Also note the proportions of pigments in the cortex in relation to hair color.

? Which of the hair layers illustrated here corresponds to the scales seen in this chapter's opening photo?

a–d: Joe DeGrandis/Ken Saladin

Pattern baldness (androgenic alopecia) is the condition in which hair is lost unevenly across the scalp rather than thinning uniformly. It results from a complex combination of polygenic inheritance, hormones (androgens), and the aforesaid environmental influences. It is about 50% to 80% hereditary. The strongest influence comes from an androgen receptor gene on the X chromosome, but at least 12 other X-linked genes and 112 autosomal ones also affect it. In genetically predisposed males, terminal hair on the scalp is replaced by thin vellus hair, beginning on top of the head and later on the sides. Females exhibit pattern baldness only if their androgen levels are abnormally high (for example, because of a tumor of the adrenal gland, a female's principal source of androgens).

Excessive or undesirable hairiness in areas that aren't usually hairy, especially in women and children, is called **hirsutism**.²⁶ It tends to run in families and usually results from either masculinizing ovarian tumors or hypersecretion of testosterone by the adrenal cortex. It is often associated with menopause.

Contrary to popular misconceptions, hair and nails don't continue to grow after a person dies, cutting hair doesn't make it grow faster or thicker, and emotional stress cannot make the hair turn white overnight.

Functions of Hair

Compared with other mammals, the relative hairlessness of humans is so unusual that it raises the question, Why do we have any hair at all? What purpose does it serve? There are different answers for the different types of hair; furthermore, some of the answers would make little sense if we limited our frame of reference to

industrialized societies, where barbers and hairdressers are engaged to alter the natural state of the hair. It is more useful to take a comparative approach to this question and consider the purposes hair serves in other species of mammals.

Most hair of the human trunk and limbs is probably best interpreted as vestigial, with little present function. Body hair undoubtedly served to keep our prehistoric ancestors warm, but in modern humans it's too scanty. Stimulation of the hair receptors, however, alerts people to parasites crawling on the skin, such as fleas and ticks. Thus, we are less likely to become unknowingly infested with parasites.

The scalp is normally the only place where the hair is thick enough to retain heat. Heat loss from a bald scalp can be substantial and quite uncomfortable. The brain receives a rich supply of warm blood, and most of the scalp lacks an insulating fat layer. Heat is easily conducted through the bones of the skull and lost to the surrounding air. In addition, without hair there is nothing to break the wind and stop it from carrying away heat. Hair also protects the scalp from sunburn, since the scalp is otherwise most directly exposed to the sun's rays. These may be the reasons humans have retained thick hair on their heads while losing most of it from the rest of the body.

Tufts and patches of hair, sometimes with contrasting colors, are important in mammals for advertising species, age, sex, and individual identity. For the less groomed members of the human species, scalp and facial hair may play a similar role. The indefinitely growing hair of a man's scalp and beard, for example, could provide a striking contrast to a face that is otherwise almost hairless. It creates a badge of recognition instantly visible at a distance.

The beard and pubic and axillary hair signify sexual maturity and aid in the transmission of sexual scents. We will further reflect

²⁶*hirsut* = shaggy

on this in a later discussion of apocrine sweat glands, whose distribution and function add significant evidence to support this theory.

Stout protective **guard hairs**, or **vibrissae** (vy-BRIS-ee), guard the nostrils and ear canals and prevent foreign particles from entering easily. The eyelashes and blink reflex shield the eye from dust and other windblown debris. The eyelashes of humans and other mammals also seem to be perfectly adapted for reducing airflow across the eye surface, thus reducing evaporation and dryness. In windy or rainy conditions, we can squint so that the eyelashes protect the eyes even further, but without completely obstructing our vision.

The eyebrows are often presumed to keep sweat or debris out of the eyes, but this seems negligible. If that is their job, they do it poorly. More likely, they function mainly to enhance facial expression. Movements of the eyebrows are an important means of non-verbal communication in humans of all cultures, and we even have special *frontalis* muscles for this purpose. Eyebrow expressiveness is not unique to humans; even monkeys and apes use quick eyebrow flashes to greet each other, assert their dominance, and break up quarrels.

6.2b Nails

Fingernails and toenails are clear, hard derivatives of the stratum corneum. They are composed of thin, dead, scaly cells, densely packed together and filled with parallel fibers of hard keratin. Most mammals have claws, whereas flat nails are one of the distinguishing characteristics of humans and other primates. Flat nails serve as strong keratinized “tools” that can be used for grooming, picking apart food, and other manipulations. In addition, they allow for more fleshy and sensitive fingertips. Imagine touching a few grains of salt on a table. The nail, by providing a counterforce or resistance from the other side, enhances one’s sensitivity to such tiny objects.

The hard part of the nail is the **nail plate** (fig. 6.10), which includes the **free edge** overhanging the tip of the finger or toe; the **nail body**, which is the visible attached part of the nail; and the **nail root**, which extends proximally under the overlying skin. The surrounding skin rises a bit above the nail as a **nail fold**, separated from the margin of the nail plate by a **nail groove**. The groove and the space under the free edge accumulate dirt and bacteria and require special attention when scrubbing for duty in an operating room or nursery.

The skin underlying the nail plate is the **nail bed**; its epidermis is called the **hyponychium**²⁷ (HIPE-o-NICK-ee-um). At the proximal end of the nail, the stratum basale thickens into a growth zone called the **nail matrix**. Mitosis in the matrix accounts for the growth of the nail—about 1 mm/week in the fingernails and slightly slower in the toenails. The thickness of the matrix obscures the underlying dermal blood vessels and is the reason why an opaque white crescent, the **lunule**²⁸ (LOON-yule), often appears at the proximal end of a nail. A narrow zone of dead skin, the **cuticle** or **eponychium**²⁹ (EP-o-NICK-ee-um), commonly overhangs this end of the nail.

FIGURE 6.10 Anatomy of a Fingernail. **APR**

The appearance of the fingertips and nails can be valuable in medical diagnosis. The fingertips become swollen or *clubbed* in response to long-term hypoxemia—a deficiency of oxygen in the blood stemming from conditions such as congenital heart defects and emphysema. Dietary deficiencies can be reflected in the appearance of the nails. An iron deficiency, for example, can cause them to become flat or concave (spoonlike) rather than convex. Contrary to popular belief, adding gelatin to the diet has no effect on the growth or hardness of the nails.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- What is the difference between vellus hair and terminal hair?
- State the functions of the hair papilla, hair receptors, and arrector muscle.
- Describe what happens in the anagen, catagen, and telogen phases of the hair cycle.
- State some reasonable theories for the different functions of hair of the eyebrows, eyelashes, scalp, nostrils, and axilla.
- Define or describe the *nail plate*, *nail fold*, *eponychium*, *hyponychium*, and *nail matrix*.

²⁷*hypo* = below; *onych* = nail

²⁸*lun* = moon; *ule* = little

²⁹*ep* = above; *onych* = nail

6.3 Cutaneous Glands

Expected Learning Outcomes

When you have completed this section, you should be able to

- name two types of sweat glands, and describe the structure and function of each;
- describe the location, structure, and function of sebaceous and ceruminous glands; and
- discuss the distinction between breasts and mammary glands, and explain their respective functions.

The skin has five kinds of glands: *eccrine sweat glands*, *apocrine sweat glands*, *sebaceous glands*, *ceruminous glands*, and *mammary glands*.

6.3a Sweat Glands

Sweat glands are of two kinds: apocrine and eccrine (compare figure 5.32). **Apocrine sweat glands** (fig. 6.11a) occur in the groin, anal region, axilla, and areola, and in mature males, in the beard area.

Axillary apocrine glands are scarce or absent from many East Asians, possibly because their ancestors, living in what is now Siberia, had little need to sweat in such a cold habitat. The absence of these glands is traceable to a mutation that arose at least 40,000 years ago. The ducts of apocrine glands lead into nearby hair follicles rather than directly to the skin surface. Apocrine glands, unfortunately, are misnamed because they don't use the apocrine mode of secretion; they use exocytosis, the same as eccrine sweat glands do. The secretory part of an apocrine gland, however, has a much larger lumen than that of an eccrine gland, so these glands continue to be called apocrine to distinguish them functionally and histologically from the eccrine type. Apocrine sweat is thicker and more milky than eccrine sweat because it contains more fatty acids.

Apocrine sweat glands are scent glands that respond especially to stress and sexual stimulation. They are not active until puberty, and in women of reproductive age, they enlarge and shrink in phase with the menstrual cycle. These facts, as well as experimental evidence, suggest that they secrete *sex pheromones*—chemicals that exert subtle effects on the sexual behavior and physiology of other people. They apparently correspond to the scent glands that develop in other mammals as they approach sexual maturity. Fresh

FIGURE 6.11 Cutaneous Glands. (a) Apocrine sweat glands have a large lumen and a duct that conveys their aromatic secretion into a hair follicle. (b) Eccrine sweat glands have a relatively narrow lumen and a duct that opens by way of a pore on the skin surface. (c) Sebaceous glands have cells that break down in entirety to form an oily secretion that is released into the hair follicle.

a–c: Dennis Strete/McGraw Hill

apocrine sweat doesn't have a necessarily disagreeable odor; indeed, it is considered attractive or arousing in some cultures, where it is as much a part of courtship as artificial perfume is to others. Disagreeable body odor is called *bromhidrosis*.³⁰ It occasionally indicates a metabolic disorder, but more often reflects inadequate hygiene.

Many mammals have apocrine scent glands associated with specialized tufts of hair. In humans, apocrine glands are found mainly in the regions covered by the pubic hair, axillary hair, and beard. This supports the interpretation that they're pheromone glands. The hair serves to retain the aromatic secretion and regulate its rate of evaporation from the skin. Thus, it seems no mere coincidence that most women's faces lack both apocrine scent glands and a beard.

Eccrine (merocrine) sweat glands (EK-rin) (fig. 6.11b) are widely distributed over the entire body, but are especially abundant on the palms, soles, and forehead. Their primary function is to cool the body. Overheating activates sweating through the sympathetic nervous system. Then, because of the high heat capacity of water (see section 2.2a), the evaporation of sweat carries away a substantial amount of body heat, cooling one down. Each is a simple tubular gland with a twisted coil in the dermis or hypodermis, and an undulating or coiled duct leading to a sweat pore on the skin surface. The duct is lined by a stratified cuboidal epithelium in the dermis and by keratinocytes in the epidermis.

In both apocrine and eccrine sweat glands, specialized **myoepithelial**³¹ cells are found amid the secretory cells at the deep end of the gland. (Such cells of the mammary gland can be seen in figure 28.9d.) They have contractile properties similar to those of smooth muscle. The sympathetic nervous system stimulates them to contract, squeeze the base of the gland, and force perspiration up the duct—particularly under conditions of overheating, nervousness, or arousal.

Sweat production begins in the deep secretory portion of the gland. Protein-free fluid filters from the blood capillaries into the lumen of the gland. Most sodium chloride is reabsorbed from the filtrate as it passes up the duct, but some remains, along with potassium, urea, lactic acid, and ammonia. Some drugs are also excreted in the perspiration. Thus, the eccrine sweat glands excrete some of the same wastes as the kidneys. The contribution of an individual sweat gland to this is minuscule, but there are 3 or 4 million eccrine sweat glands in the adult skin, with a total mass about equal to one kidney.

Perspiration is about 99% water and has a pH ranging from 4 to 6, contributing the earlier-mentioned *acid mantle* that inhibits bacterial growth on the skin. Usually, perspiration evaporates about as fast as it is produced, so it isn't noticed; this is called **insensible perspiration**. But under such conditions as heat, exercise, and circulatory shock, more copious sweat is produced and noticeably wets the skin; this is called **diaphoresis**³² (DY-uh-foe-REE-sis). Insensible perspiration typically amounts to about 500 mL/day, but in diaphoresis, a person can lose a liter or more of

sweat per hour. In heavy sweating, fluid loss from the bloodstream can be so great as to cause circulatory shock. Sweating, however, isn't the only way the skin loses water. A significant amount also diffuses between the keratinocytes and evaporates from the skin surface—a process called *cutaneous transpiration*.

6.3b Sebaceous Glands

Sebaceous³³ glands (see-BAY-shus) produce an oily secretion called **sebum** (SEE-bum). They are flask-shaped, with short ducts that usually open into a hair follicle (fig. 6.11c), although some of them open directly onto the skin surface. These are holocrine glands with little visible lumen. Their secretion consists of broken-down cells that are replaced by mitosis at the base of the gland. Sebum keeps the skin and hair from becoming dry, brittle, and cracked. The sheen of well-brushed hair is due to sebum distributed by the hairbrush. Ironically, some go to great lengths to wash sebum from the skin, only to replace it with various skin creams and hand lotions made of little more than lanolin, which is sheep sebum.

6.3c Ceruminous Glands

Ceruminous glands (seh-ROO-mih-nus) are modified apocrine glands found only in the external ear canal. Their yellow, waxy secretion combines with sebum and dead epidermal cells to form earwax, or **cerumen**.³⁴ They are coiled, simple tubular glands with ducts leading to hair follicles or the skin surface of the ear canal. Cerumen keeps the eardrum pliable, waterproofs the canal, kills bacteria, and coats the guard hairs of the ear, making them sticky and more effective in blocking foreign particles from entering the canal.

6.3d Mammary Glands

The **mammary glands** and breasts (*mammæ*) are often mistakenly regarded as one and the same. Breasts, however, are present in both sexes, and even in females they rarely contain more than small traces of mammary gland. The mammary glands, by contrast, are the milk-producing glands that develop within the female breast during pregnancy and lactation. They are modified apocrine sweat glands that produce a richer secretion and channel it through ducts to a nipple for more efficient conveyance to the offspring. The anatomy and physiology of the mammary gland are discussed in more detail in chapter 28.

In most mammals, two rows of mammary glands form along lines called the *mammary ridges*, or *milk lines*. Primates have dispensed with all but two of these glands. A few people of both sexes, however, develop additional nipples or *mammæ* along the milk line inferior to the primary *mammæ*. In the Middle Ages and colonial America, this condition, called *polythelia*,³⁵ was used to incriminate women as supposed witches.

The glands of the skin are summarized in **table 6.2**.

³⁰*brom* = stench; *hidros* = sweat

³¹*myo* = muscle

³²*dia* = through; *phoresis* = carrying

³³*seb* = fat, tallow; *aceous* = possessing

³⁴*cer* = wax

³⁵*poly* = many; *theli* = nipples

TABLE 6.2 Cutaneous Glands	
Gland Type	Definition
Sweat glands	Glands that produce perspiration
Eccrine glands	Sweat glands that function in evaporative cooling; widely distributed over the body surface; open by ducts onto the skin surface
Apocrine glands	Sweat glands that function as scent glands; found in the regions covered by the pubic, axillary, and male facial hair; open by ducts into hair follicles
Sebaceous glands	Oil glands associated with hair follicles
Ceruminous glands	Glands of the ear canal that contribute to the cerumen (earwax)
Mammary glands	Milk-producing glands located in the breasts

BEFORE YOU GO ON

- Answer the following questions to test your understanding of the preceding section:
- 12. How do eccrine and apocrine sweat glands differ in structure and function?
 - 13. What other type of gland is associated with hair follicles? How does its mode of secretion differ from that of sweat glands?
 - 14. What is the difference between the breast and mammary gland?

6.4 Skin Disorders

Expected Learning Outcomes

- When you have completed this section, you should be able to
- a. describe the three most common forms of skin cancer; and
 - b. describe the three classes of burns and the priorities in burn treatment.

Because it is the most exposed of all our organs, skin is not only the most vulnerable to injury and disease, but it is also the one place where we are most likely to notice anything out of the ordinary. Skin diseases become increasingly common in old age, and most people over age 70 have complaints about their integumentary system. Aging of the skin is discussed more fully in chapter 29. The healing of cuts and other injuries to the skin occurs by the process described in chapter 5. We focus here on two particularly common and serious disorders: skin cancer and burns. Other skin diseases are briefly summarized in **table 6.3**.

6.4a Skin Cancer

Skin cancer befalls about one out of five people in the United States at some time in their lives. Most cases are caused by UV radiation from the sun, which damages DNA and disables protective tumor suppressor genes in the epidermal cells. Consequently, most tumors occur on the head, neck, and hands, where exposure to the sun is greatest. It is most common in fair-skinned people and the elderly, who have had the

longest lifetime UV exposure (see Deeper Insight 6.3). The ill-advised popularity of suntanning, however, has caused an alarming increase in skin cancer among younger people. Skin cancer is one of the most common cancers, but it is also one of the easiest to treat and has one of the highest survival rates when it is detected and treated early.

▶▶▶ APPLY WHAT YOU KNOW

Skin cancer is relatively rare in people with dark skin. Other than possible differences in behavior, such as less intentional suntanning, why do you think this is so?

There are three types of skin cancer named for the epidermal cells in which they originate: *basal cell carcinoma*, *squamous cell carcinoma*, and *melanoma*. The three types are also distinguished from each other by the appearance of their **lesions**³⁶ (zones of tissue injury).

Basal cell carcinoma³⁷ (**fig. 6.12a**) is the most common type. It is the least deadly because it seldom metastasizes, but if neglected, it can severely disfigure the face. It arises from cells of the stratum basale and eventually invades the dermis. On the surface, the lesion first appears as a small, shiny bump. As the bump enlarges, it often develops a central depression and a beaded pearly edge.

Squamous cell carcinoma (**fig. 6.12b**) arises from keratinocytes of the stratum spinosum. Lesions usually appear on the scalp, ears, lower lip, or back of the hand. They have a raised, reddened, scaly appearance, later forming a concave ulcer with raised edges. The chance of recovery is good with early detection and surgical removal, but if it goes unnoticed or is neglected, this cancer tends to metastasize to the lymph nodes and can be lethal.

Melanoma (**fig. 6.12c**) is a skin cancer that arises from the melanocytes. It accounts for no more than 5% of skin cancers, but it is the sixth most frequently diagnosed cancer in the United States and is extremely aggressive. It can be treated surgically if caught early, but if it metastasizes—which it does quickly—it is unresponsive to chemotherapy. The prognosis for metastatic melanoma has generally been grim, with the average patient living only 6 months after diagnosis and only 27% surviving for 5 years. Hope is arising, however, from new targeted therapies for melanoma. One of these treatments uses the radioisotope rhenium-188 (¹⁸⁸Re) bonded to melanocyte-stimulating hormone (MSH). MSH selectively binds to melanocyte receptors, thus accumulating selectively in the very cells that compose metastatic melanoma. ¹⁸⁸Re emits alpha particles, a highly potent ionizing radiation that is lethal to the tumor cells. Yet alpha particles are too large and heavy to penetrate very far, and are thus relatively harmless to healthy cells around the tumor. ¹⁸⁸Re, bound to other peptides, has also been used to treat liver cancer and is in clinical trials for pancreatic cancer.

The greatest risk factors for melanoma are ancestry, skin color, sex, family history of the disease, and behavior (sun exposure). The incidence of melanoma varies greatly with ancestry and color. Recent U.S. data show, for every 100,000 people, 28.0 cases in white non-Hispanic, 5.6 in Native American, 4.6 in white Hispanic, 1.3 in Asian, and 1.0 in Black individuals. In all groups, the incidence and mortality rates are significantly higher in males than in females. About two-thirds of cases of melanoma in males result

³⁶lesio = injure
³⁷carcin = cancer; oma = tumor

FIGURE 6.12 Skin Cancer. (a) Basal cell carcinoma. (b) Squamous cell carcinoma. (c) Melanoma.

? Which of the ABCDE rules can you identify in part (c)?

a: jax10289/Shutterstock; b: Dr. P. Marazzi/Science Photo Library/Alamy Stock Photo; c: National Cancer Institute (NCI)

from an oncogene called *BRAF*. In females, *BRAF* doesn't appear to trigger melanoma, but it has been linked to some breast and ovarian cancers. *BRAF* mutations are commonly found in moles.

Only about one-quarter of melanomas arise from moles, but it is important, anyway, to distinguish a mole from a melanoma. A mole usually has a uniform color and even contour, and it is no larger in diameter than the eraser of a new wooden pencil (about 6 mm). If it becomes malignant, however, it forms a large, flat, spreading lesion with a scalloped border. The American Cancer Society suggests an “ABCDE rule” for recognizing melanoma: *A* for asymmetry (irregular shape, unlike the rounded lesions of the other forms of skin cancer); *B* for border irregularity (the contour is not smooth but wavy or scalloped); *C* for color (often a mixture of brown, black, tan, and sometimes red and blue); *D* for diameter (greater than 6 mm); and *E* for evolving (changing size, shape, or color). Melanoma can also occur beneath the fingernails and toenails, where a brown or black area under the nail should be regarded with concern.

Depending on the type of cancer and its location (local lesion or metastatic spread), skin cancers are treated by surgical excision, radiation therapy, or destruction of the lesion by heat (electrodesiccation) or cold (cryosurgery).

6.4b Burns

Burns are usually caused by fires, kitchen spills, or excessively hot bath water, but they also can be caused by sunlight, ionizing radiation, strong acids and bases, or electrical shock. Burn deaths result primarily from fluid loss, infection, and the toxic effects of **eschar** (ESS-car)—the burned, dead tissue.

Burns are classified according to the depth of tissue involvement. **First-degree burns** (fig. 6.13a) involve only the epidermis and are marked by redness, slight edema, and pain. They heal in a few days and seldom leave scars. Most sunburns are first-degree burns.

Second-degree burns (fig. 6.13b) involve the epidermis and part of the dermis but leave at least some of the dermis intact. First- and second-degree burns are therefore also known as **partial-thickness burns**. A second-degree burn may be red, tan, or white and is blistered and very painful. It may take from 2 weeks to several months to heal and may leave scars. The epidermis regenerates by division of epithelial cells in the hair follicles and sweat glands and around the edges of the lesion. Severe sunburns and many scalds are second-degree burns.

Third-degree burns (fig. 6.13c) are a leading cause of accidental death. They are also called **full-thickness burns** because the epidermis, all of the dermis, and often some deeper tissues (muscle and bone) are destroyed. (Some authorities call burns that extend to the bone *fourth-degree burns*.) Since no dermis remains, the skin can regenerate only from the edges of the wound. Third-degree burns often require skin grafts (see Deeper Insight 6.2). If a third-degree burn is left to itself to heal, contracture (abnormal connective tissue fibrosis) and disfigurement may result.

▶▶▶ APPLY WHAT YOU KNOW

A third-degree burn may be surrounded by painful areas of first- and second-degree burns, but the region of the third-degree burn is painless. Explain the reason for this lack of pain.

FIGURE 6.13 Burns. (a) First-degree burn, involving only the epidermis. (b) Second-degree burn, involving the epidermis and part of the dermis and often with blistering. (c) Third-degree burn, extending through the entire dermis and often involving even deeper tissue.

a: Dmitrii Kotin/Alamy Stock Photo; b: thawatchai_bandit/Shutterstock; c: Anukool Manoton/Shutterstock

The two most urgent considerations in treating a burn patient are fluid replacement and infection control. A patient can lose several liters of water, electrolytes, and protein each day from the burned area. As fluid is lost from the tissues, more is transferred from the bloodstream to replace it, and the volume of circulating blood declines. A patient may lose up to 75% of the blood plasma within a few hours, potentially leading to circulatory shock and cardiac arrest—the principal cause of death in burn patients. Intravenous fluid must be given to make up for this loss. A severely burned patient may also require thousands of extra calories daily to compensate for protein loss and the demands of tissue repair. Supplemental nutrients are given intravenously or via gastric tube.

Infection is controlled by keeping the patient in an aseptic (germ-free) environment and administering antibiotics. The eschar is sterile for the first 24 hours, but then it quickly becomes infected and may have toxic effects on the digestive, respiratory, and other

systems. Its removal, called **debridement**³⁸ (deh-BREED-ment), is essential to infection control.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

15. What types of cells are involved in each type of skin cancer?
16. Which type of skin cancer is most dangerous? What are its early warning signs?
17. What are the differences between first-, second-, and third-degree burns?
18. What are the two most urgent priorities in treating a burn victim? How are these needs addressed?

³⁸de = un; bride = bridle

TABLE 6.3 Some Disorders of the Integumentary System

Acne	Inflammation of the sebaceous glands, especially beginning at puberty; follicle becomes blocked with keratinocytes and sebum and develops into a whitehead (<i>comedo</i>) composed of these and bacteria; continued inflammation of follicle results in pus production and appearance of pimples, and oxidation of sebum turns a whitehead into a blackhead.
Dermatitis	Any inflammation of the skin, typically marked by itching and redness; often <i>contact dermatitis</i> , caused by exposure to toxic foliage such as poison ivy.
Eczema (ECK-zeh-mah)	Itchy, red, “weeping” skin lesions caused by an allergy, usually beginning before age 5; may progress to thickened, leathery, darkly pigmented patches of skin.
Psoriasis (so-RY-ah-sis)	Recurring, reddened plaques covered with silvery scale; sometimes disfiguring; possibly caused by an autoimmune response; runs in families.
Rosacea (ro-ZAY-she-ah)	A red rashlike area, often in the area of the nose and cheeks, marked by fine networks of dilated blood vessels; worsened by hot drinks, alcohol, and spicy food.
Seborrheic dermatitis (seb-oh-REE-ik)	Recurring patches of scaly white or yellowish inflammation often on the head, face, chest, and back; called <i>cradle cap</i> (a yellow, crusty scalp lesion) in infants. Cause unknown, but correlated with genetic and climatic factors.
Tinea	Any fungal infection of the skin; common in moist areas such as the axilla, groin, and foot (<i>athlete’s foot</i>). Misnamed <i>ringworm</i> because of the circular, wormlike growth pattern sometimes exhibited.

You can find other integumentary system disorders described in the following places:

Genital warts in Deeper Insight 27.5; and in the present chapter, *pathological skin colors* and *birthmarks* in sections 6.1e and 6.1f; *baldness* and *hirsutism* in section 6.2a; *polythelia* in section 6.3d; and *skin cancer* and *burns* in section 6.4.

DEEPER INSIGHT 6.3
CLINICAL APPLICATION

UVA, UVB, and Sunscreens

The usual culprit blamed for sunburns and skin cancer is the ultraviolet (UV) radiation in sunlight. Not all UV rays are the same, however. UV is divided into two wavelength ranges, UVA and UVB. UVA, so-called “tanning rays,” have the longer wavelength (320–400 nm) and lower energy of the two. UVA lies just below the visible spectrum of light, where 400 nm is on the borderline between black and the deepest violet we can see. UVB, so-called “burning rays,” have a shorter wavelength (290–320 nm) and higher energy level. Tanning salons often advertise that they only use “safe” UVA rays, but public health authorities are skeptical. UVA can burn as well as tan, it is responsible for most of the undesirable photoaging effects on the skin (see section 29.4a), and it inhibits one’s immune system. Both UVA and UVB are now thought to initiate skin cancer. As dermatologists like to say, there is no such thing as a healthy tan.

Many people buy sunscreen according to its sun protection factor (SPF), but may be misled by the concept. SPF is a laboratory measure of protection from UVB radiation. It is advisable to use a minimum SPF of 15 for meaningful protection. It might seem that an SPF of 30 would give twice as much protection as SPF 15, but the relationship between protection and SPF isn’t linear. An SPF 15 sunscreen protects the skin from 93% of UVB, but SPF 30 protects only slightly more—97%. Although manufacturers compete to produce high-SPF products, higher numbers

create a false sense of much greater protection. The Australian government considers SPF values above 30 to be misleading.

Furthermore, effectiveness varies with the amount applied, frequency of reapplication, skin type, and sweating, and sunscreen is washed off by swimming. People tend to use only one-quarter to one-half as much as needed to provide the SPF rating on the label, and wait too long between reapplications. For effective protection, one should divide the SPF by 2 and reapply sunscreen that many minutes after the onset of sun exposure—that is, every 15 minutes for an SPF of 30. Some products claim “broad spectrum UVA/UVB protection,” but there is no good evidence that they protect adequately against UVA.

It was once assumed that sunscreens protect against skin cancer, but more careful studies have called this into question. Sunburn and skin cancer are caused by different mechanisms, and even if sunscreen protects against burning, it may provide little protection against cancer. Ironically, as the sale of sunscreen has risen, so has the incidence of skin cancer—perhaps because people falsely assume that when they use sunscreen, they can safely stay in the sun longer. Some evidence suggests that a debatably small contribution of UV to skin cancer is overridden by its much greater protective effect against numerous disorders as diverse as diabetes, hypertension, stroke, depression, osteoporosis, and obesity.

DEEPER INSIGHT 6.4

EVOLUTIONARY MEDICINE

The Evolution of Skin Color

Most variation in human skin color is the result of evolutionary selection pressures that acted on the species as humans migrated from Africa and colonized the world, starting around 100,000 years ago.

Ultraviolet radiation (UVR) in the tropics is intense. Our australopithecine ancestors probably, like other primates today, had light skin under heavy dark fur that protected them from the damaging effects of UVR. Our earliest ancestors of the genus *Homo*, however, were bipedal primates adapted for long-distance walking and running. That came with a danger of overheating, so it was accompanied by great reduction in body hair, allowing body heat to dissipate more easily, and the evolution of sweat glands for evaporative cooling. Hair loss, however, created another problem to deal with—exposure of light-colored skin to the damaging effects of UVR. The skin had to protect itself from excess radiation—a strong selection pressure favoring melanization in the tropics. Brown and black skin today have an SPF of about 10 to 15, and white skin only 2.5 (compare the SPFs of sunscreens in Deeper Insight 6.3).

UVR brings both dangers and benefits, though, so its actions on human evolution were anything but simple. On one hand, it stimulates the epidermis to produce **vitamin D** (see fig. 7.16), which is essential for calcium metabolism, cell growth, neuromuscular and immune function, and perhaps most notably, bone health and fetal and childhood development. Worldwide, women's skin averages about 4% lighter than men's, perhaps because of the greater need in women for vitamin D and calcium to support pregnancy and lactation. Vitamin D is also necessary to healthy children because it prevents a bone defect known as *rickets* (see fig. 7.15).

But on the other hand, the damaging effects of excess UVR are well known—sunburn and skin cancer especially. It also generates free radicals that destroy the immune dendritic cells of the epidermis, damage proteins and DNA, and accelerate the photoaging of skin. But the only factor relevant to evolution is reproductive success, and excess UVR (especially UVA) can exert a powerfully negative effect here. It degrades not only DNA but also **folate**, a B vitamin. Folate is necessary to cell division, therefore crucial to both sperm and egg production and embryonic development. A folate deficiency can cause infertility, severe birth defects such as *spina bifida*, and prenatal death. This is a powerful selection pressure favoring especially dark, protective skin in latitudes where UVR is strongest.

As humans migrated out of Africa and into Asia and Europe, they settled at latitudes with much weaker sunlight than the tropics. There, excessively dark, UV-blocking skin became a liability, interfering with the synthesis of vitamin D. The farther north or south one goes from the tropics, the weaker the sunlight is, and the more important it is to have lighter skin. Most of the world's land mass is north of the equator, so this effect was most pronounced in Europe and Asia. Migration into the American continents came much later.

The evolution of skin color in response to migration thus represents a compromise between the needs for folate (degraded by UVR) and vitamin D (promoted by UVR). Too much UVR, and a population suffers reduced reproductive success because of folate degradation; too little, and it suffers reduced reproductive success because of vitamin D deficiency. This accounts for most variation in ancestral skin colors in

FIGURE 6.14 Distribution of Ancestral Skin Colors in the Eastern Hemisphere. Predicted from UV radiation and other environmental factors.

top: harpazo hope/Getty Images; bottom: ManoAfrica/E+/Getty Images

relation to latitude, where we see a hereditary gradient of color (a *cline* in evolutionary terms) from tropical to boreal latitudes (fig. 6.14).

In regions with large seasonal variations in UVR, evolution has selected for **tanning**—the ability to darken the skin and protect folate and DNA when UVR is intense, and to lighten the skin to ensure adequate vitamin D synthesis when the UVR is weaker. Tanning ability is especially pronounced in people of Mediterranean descent.

Yet the geographic distribution of color isn't that simple. Over the last few thousand years, humans have migrated from their ancestral lands into new latitudes faster than evolution can keep pace. The invention of shelter and clothing also protects the skin from a great deal of UVR and its selective effects. In far northern latitudes, one might expect lighter skin than we see in the Inuit–Aleut–Eskimo people of northern circumpolar regions. Here, however, the intense reflection of UVR from snow favors melanization; winter sports enthusiasts are well aware of the potential sunburning effect of reflection from snow and ice. Altitude also comes into play. UVR increases at higher elevations where the thin, dry atmosphere filters out less UVR. This helps to explain the darker skin of people indigenous to such localities as the Andes Mountains and the high plateaus of Tibet and Ethiopia, as well as in deserts from the Sonoran to the Mideast to the Gobi. The evolution of skin color is also influenced by intermarriage among people of different geographic ancestries, and by darwinian *sexual selection*—a preference for mates of light or dark complexion, thereby perpetuating and accentuating ethnic differences in color.

Skin-lightening mutations have occurred independently at multiple times and locations throughout human migration and evolution, and with no relation to other ethnic traits. For this and other reasons, it makes no sense to think of *White* or *Black* as “races.” The concept of race is biologically meaningless and largely discarded from contemporary scientific thought.

SYSTEM CONNECTIONS

Effects of the **INTEGUMENTARY SYSTEM** on Other Organ Systems

ALL SYSTEMS

Skin covers the body and provides a barrier to pathogens and to excessive water loss; epidermal keratinocytes initiate synthesis of calcitriol, with effects on multiple other organ systems as noted.

SKELETAL SYSTEM

Bone growth and maintenance depend on calcium, which is absorbed from the diet under the influence of calcitriol.

LYMPHOID AND IMMUNE SYSTEMS

Dendritic cells of the skin alert the immune system when pathogens breach the epidermal barrier.

MUSCULAR SYSTEM

Muscle contraction depends on calcium, which is absorbed from the diet under the influence of calcitriol.

RESPIRATORY SYSTEM

Nasal guard hairs block some airborne debris from being inhaled; calcium is required for the secretion of respiratory mucus, which therefore depends on calcitriol.

NERVOUS SYSTEM

The transmission of nerve signals across synapses depends on calcium, which is absorbed from the diet under the influence of calcitriol.

URINARY SYSTEM

Skin complements the urinary system by excreting salts and some nitrogenous waste in the sweat; calcitriol promotes reabsorption of calcium by the kidneys.

ENDOCRINE SYSTEM

Hormone secretion depends on calcium as a trigger for exocytosis and, therefore, on calcitriol; the role of epidermal keratinocytes in synthesizing calcitriol is itself an endocrine function.

DIGESTIVE SYSTEM

By their role in calcitriol synthesis, keratinocytes influence intestinal absorption of calcium; calcium is needed for the secretion of all digestive enzymes and mucus.

CIRCULATORY SYSTEM

The skin is a major blood reservoir; cutaneous vasoconstriction diverts blood to other organs; skin supports blood volume by retarding fluid loss; dermal vasoconstriction and vasodilation help to regulate blood temperature.

REPRODUCTIVE SYSTEM

Cutaneous nerve endings are important in sexual stimulation; mammary glands produce milk; apocrine sweat glands secrete pheromones that affect sexual behavior and physiology; skin stretches to accommodate abdominal growth in pregnancy.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

6.1 The Skin and Subcutaneous Tissue

1. The name of the branch of medicine that deals with the integumentary system
2. The difference between the terms *integumentary system* and *integument*; organs that belong to the integumentary system
3. The two principal layers of the skin, and the name of the connective tissue layer that lies between the skin and the deeper muscle or other tissue
4. Normal thickness of the skin, and differences in histology and location between thick and thin skin
5. Functions of the skin
6. Five histological layers of thick skin and which of them is lacking from thin skin
7. Five kinds of epidermal cells, their respective functions, and the epidermal layers in which they occur
8. The life history of a keratinocyte from the time it is “born” by mitosis at the base of the epidermis to the time it exfoliates from the surface
9. Fiber and cell types of the dermis, other dermal structures, and the typical thickness of the dermis

10. Dermal papillae, epidermal ridges, their function, and their relationship to the surface appearance of skin
11. The two layers of the dermis, and how they differ histologically and functionally
12. Composition and functions of the hypodermis, and an alternative name for it when it is composed predominantly of adipose tissue
13. Factors that account for the variety of normal skin colors; abnormal skin colors and their causes
14. Friction ridges, flexion lines, freckles, moles, and hemangiomas

6.2 Hair and Nails

1. How the keratin of hair and nails differs from keratin of the epidermis
2. Three kinds of hair, including fetal and adult types
3. The three regions of a hair from base to tip, and the three layers of a hair from core to surface
4. Location of a hair’s growth zone and of its source of nourishment
5. The two layers of a hair follicle; their composition; and the specialized nerve endings and smooth muscle associated with a follicle
6. The basis for differences between straight, wavy, and curly hair and for differences in hair color

7. Events of the anagen, catagen, and telogen stages of a hair’s life; the typical life span and growth rate of scalp hairs
8. Alopecia, pattern baldness, and hirsutism
9. Functions and body distribution of the various kinds of hair
10. The anatomy of fingernails and toenails; location of their growth zone; and a typical rate of nail growth

6.3 Cutaneous Glands

1. Apocrine and eccrine sweat gland distribution, development, structure, and function
2. The same characteristics of sebaceous glands; the name of their product; and how their mode of secretion differs from that of the sweat glands
3. Ceruminous gland distribution, development, structure, and function
4. Mammary gland structure and development and how mammary glands relate to a type of sweat glands

6.4 Skin Disorders

1. Three forms of skin cancer and differences in their appearance, the cells in which they originate, their frequency of occurrence, and their severity
2. Three degrees of burns and how they are treated

► Testing Your Recall

Answers in Appendix A

1. Cells of the _____ are keratinized and dead.
 - a. papillary layer
 - b. stratum spinosum
 - c. stratum basale
 - d. stratum corneum
 - e. stratum granulosum
2. The epidermal water barrier is formed at the point where epidermal cells
 - a. pass from stratum basale to stratum spinosum.
 - b. enter the telogen phase.
 - c. pass from stratum spinosum to stratum granulosum.
 - d. form the epidermal ridges.
 - e. exfoliate.
3. Which of the following skin conditions or appearances would most likely result from liver failure?
 - a. pallor
 - b. erythema
 - c. seborrheic dermatitis
 - d. jaundice
 - e. melanization
4. All of the following interfere with microbial invasion of the body *except*
 - a. the acid mantle.
 - b. melanization.
 - c. dendritic cells.
 - d. keratinization.
 - e. sebum.
5. The hair on a 6-year-old’s arms is
 - a. vellus hair.
 - b. terminal hair.
 - c. alopecia.
 - d. downy hair.
 - e. rosacea.
6. Which of the following terms is *least* related to the rest?
 - a. lunule
 - b. nail plate
 - c. hyponychium
 - d. free edge
 - e. cortex

STUDY GUIDE

7. Which of the following is a scent gland?
 - a. eccrine gland
 - b. sebaceous gland
 - c. apocrine gland
 - d. ceruminous gland
 - e. eccrine gland
8. _____ are skin cells with a sensory role.
 - a. Tactile cells
 - b. Dendritic cells
 - c. Stem cells
 - d. Melanocytes
 - e. Keratinocytes
9. Which of the following glands produce the acid mantle?
 - a. eccrine sweat glands
 - b. apocrine sweat glands
 - c. mammary glands
 - d. ceruminous glands
 - e. sebaceous glands
10. Which of the following skin cells alert the immune system to pathogens?
 - a. fibroblasts
 - b. melanocytes
 - c. keratinocytes
 - d. dendritic cells
 - e. tactile cells
11. _____ is sweating without noticeable wetness of the skin.
12. A muscle that causes a hair to stand on end is called a/an _____.
13. The process of removing burned skin from a patient is called _____.
14. Blueness of the skin and mucous membranes due to low oxygen concentration in the blood is called _____.
15. Projections of the dermis toward the skin surface are called _____.
16. Cerumen is more commonly known as _____.
17. The holocrine glands that secrete into a hair follicle are called _____.
18. Hairs grow only during the _____ phase of the hair cycle.
19. A hair is nourished by blood vessels in a connective tissue projection called the _____.
20. A _____ burn destroys the entire dermis.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|----------|-------------|------------|
| 1. -in | 3. dermato- | 7. melano- |
| 2. albo- | 4. dia- | 8. -oma |
| | 5. homo- | 9. onycho- |
| | 6. lesio- | 10. pilo- |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|--|---|---|
| 1. Basal cell carcinoma is the rarest form of skin cancer and the least likely to metastasize. | 4. Vitamin D synthesis begins in certain cutaneous glands. | 8. People of African descent have a much higher density of epidermal melanocytes than do people of northern European descent. |
| 2. Male pattern baldness is caused by a recessive allele on the Y chromosome. | 5. Epidermal cells multiply rapidly in the stratum granulosum to produce the thick, protective stratum corneum. | 9. Pallor indicates a genetic lack of melanin. |
| 3. The dermis is composed mainly of keratin. | 6. The hair cuticle is composed of dead cells; the living hair cells constitute the cortex. | 10. Eccrine and apocrine sweat glands are present from birth. |
| | 7. The three layers of the skin are the epidermis, dermis, and hypodermis. | |

► Testing Your Comprehension

- | | | |
|--|--|--|
| 1. Many organs of the body contain numerous smaller organs, perhaps even thousands. Describe an example of this in the integumentary system. | evolution. Discuss examples of this in the integumentary system. | 4. Cold weather does not normally interfere with oxygen uptake by the blood, but it can cause cyanosis anyway. Why? |
| 2. Certain aspects of human form and function are easier to understand when viewed from the perspective of comparative anatomy and | 3. Explain how the complementarity of form and function is reflected in the fact that the dermis has two histological layers and not just one. | 5. Why is it important for the epidermis to be effective, but not <i>too</i> effective, in screening out UV radiation? |

Module 5: Skeletal System

BRUSHING UP

- Bones develop from an embryonic connective tissue called mesenchyme, described in section 5.1b.
- Hyaline cartilage histology (see table 5.7) is important for understanding bone development and certain features of the mature skeleton.
- Review stem cells (section 5.6c) to best understand bone cells and their origins.

In art and history, nothing has so often symbolized death as a skull or skeleton.¹ Bones and teeth are the most durable remains of a once-living body and the most vivid reminder of the impermanence of life.

The dry bones presented for laboratory study may wrongly suggest that the skeleton is a nonliving scaffold for the body, like the steel girders of a building. Seeing it in such a sanitized form makes it easy to forget that the living skeleton is made of dynamic tissues, full of cells—that it continually remodels itself and interacts physiologically with all of the other organ systems of the body. The skeleton is permeated with nerves and blood vessels, which attests to its sensitivity and metabolic activity.

Osteology,² the study of bone, is the subject of these next three chapters. In this chapter, we study bone as a tissue—its composition, its functions, how it develops and grows, how its metabolism is regulated, and some of its disorders. This will provide a basis for understanding the skeleton, joints, and muscles in the chapters that follow.

7.1 Tissues and Organs of the Skeletal System

Expected Learning Outcomes

When you have completed this section, you should be able to

- name the tissues and organs that compose the skeletal system;
- state several functions of the skeletal system;
- distinguish between bone as a tissue and as an organ; and
- describe the general features of a long bone and a flat bone.

The **skeletal system** is composed of bones, cartilages, and ligaments joined tightly to form a strong, flexible framework for the body. Cartilage, the forerunner of most bones in embryonic and childhood development, covers many joint surfaces in the mature skeleton. Ligaments hold bones together at the joints and are discussed in chapter 9. Tendons are structurally similar to ligaments

but attach muscle to bone; they are discussed with the muscular system in chapter 10. Here, we focus on the bones.

7.1a Functions of the Skeleton

The skeleton plays at least seven roles:

1. **Support.** Bones of the limbs and vertebral column support the body; the mandible and maxilla support the teeth; and some viscera are supported by nearby bones.
2. **Protection.** Bones enclose and protect the brain, spinal cord, heart, lungs, pelvic viscera, and bone marrow.
3. **Movement.** Limb movements, breathing, and other movements are produced by the action of muscles on the bones.
4. **Electrolyte balance.** The skeleton stores calcium and phosphate ions and releases them into the tissue fluid and blood according to the body's physiological needs.
5. **Acid–base balance.** Bone tissue buffers the blood against excessive pH changes by absorbing or releasing alkaline phosphate and carbonate salts.
6. **Blood formation.** Red bone marrow is the major producer of blood cells, including cells of the immune system.
7. **Hormone secretion.** Bone cells secrete hormones that influence the secretion and action of insulin and moderate the stress response.

7.1b Bones and Osseous Tissue

Bone, or **osseous**³ **tissue**, is a connective tissue in which the matrix is hardened by the deposition of calcium phosphate and other minerals. The hardening process is called **mineralization** or **calcification**. (Bone isn't the hardest substance in the body; that distinction goes to tooth enamel.) Osseous tissue is only one of the tissues that make up a bone. Also present are blood, bone marrow, cartilage, adipose tissue, nervous tissue, and fibrous connective tissue. The word *bone* can denote an organ composed of all these tissues, or it can denote just the osseous tissue.

7.1c General Features of Bones

Bones have a wide variety of shapes correlated with their varied protective and locomotor functions. Most of the cranial bones are in the form of thin curved plates called **flat bones**, such as the paired parietal bones that form the dome of the top of the head. The sternum (breastbone), scapula (shoulder blade), ribs, and hip bones are also flat bones. The most important bones in movement are the **long bones** of the limbs—the humerus, radius, and ulna of the arm and forearm; the femur, tibia, and fibula of the thigh and leg; and the metacarpals, metatarsals, and phalanges of the hands and feet. Like crowbars, long bones serve as rigid levers that are acted upon by skeletal muscles to produce the major body movements. Various bones that don't fit the flat or long

¹*skelet* = dried up

²*osteo* = bone; *logy* = study of

³*os, osse, oste* = bone

bone groups are sometimes called *short bones* (such as those of the wrist and ankle) or *irregular bones* (such as the vertebrae and some skull bones).

Figure 7.1 shows the general anatomy of a long bone. Much of it is composed of an outer shell of dense white osseous tissue called **compact, dense, or cortical bone**. The shell encloses a space called the **marrow (medullary) cavity** (MED-you-lerr-ee), which contains bone marrow. At the ends of the bone, the central space is occupied by a more loosely organized form of osseous tissue called **spongy (cancellous) bone**. A narrow zone of spongy bone also occurs just inside the cortical bone of the shaft and in the middle of most flat, irregular, and short bones. The skeleton is about three-quarters compact bone and one-quarter spongy bone in dry weight. Spongy bone is always enclosed by a shell of more durable compact bone.

The principal features of a long bone are its shaft, called the **diaphysis**⁴ (dy-AF-ih-sis), and an expanded head at each end called the **epiphysis**⁵ (eh-PIF-ih-sis). The diaphysis provides leverage, and the epiphysis is enlarged to strengthen the joint and provide added surface area for the attachment of tendons and ligaments. Mature bones often exhibit an *epiphyseal line* of slightly denser spongy bone between the epiphysis and diaphysis. This is a remnant of a childhood growth zone called an *epiphyseal plate*, detailed later. The joint surface where one bone meets another is covered with a layer of hyaline cartilage called the **articular cartilage**. Together with a lubricating fluid secreted between the bones, this cartilage enables a joint to move far more easily than it would if one bone rubbed directly against the other. Blood vessels penetrate into the bone through minute holes called **nutrient foramina** (for-AM-ih-nuh); we will trace where they go when we consider the histology of bone.

Externally, a bone is covered with a sheath called the **periosteum**.⁶ You could think of the periosteum as analogous to the inedible casing one peels off a sausage; the casing is to the sausage what the periosteum is to a bone—a tough surface membrane. It is composed of an outer *fibrous layer* of collagen and an inner *osteogenic layer* of bone-forming cells described in the next section. Some collagen fibers of the outer layer are continuous with the tendons that bind muscle to bone, and some penetrate into the bone matrix as **perforating fibers**. The periosteum thus provides strong attachment and continuity from muscle to tendon to bone. The osteogenic layer is important to the growth of bone and healing of fractures. There is no periosteum over the articular cartilage.

A thin layer of reticular connective tissue called the **endosteum**⁷ lines the internal marrow cavity, covers all the honey-combed surfaces of spongy bone, and lines a canal system found throughout the compact bone.

Flat bones are shieldlike plates that protect delicate organs such as the brain and heart and form broad surfaces for muscle attachment, such as the scapula and hip bones. They have a sandwichlike construction with two layers of compact bone, called the

FIGURE 7.1 Anatomy of a Long Bone. (a) The femur, with its soft tissues including bone marrow, articular cartilage, blood vessels, and periosteum. (b) A dried femur in longitudinal section. Most teaching specimens are dead, dried bones and give a very limited impression of what a bone is like in the living body.

? What is the functional significance of a long bone being wider at the epiphyses than at the diaphysis?

inner and outer tables, enclosing a middle layer of spongy bone (**fig. 7.2**). The spongy layer in the cranium is called **diploe**⁸ (DIP-lo-ee). A moderate blow to the skull can fracture the outer table of compact bone, but the diploe can sometimes absorb the impact and leave the inner table and brain unharmed. Both surfaces of a flat bone are covered with periosteum, and the marrow spaces amid the spongy bone are lined with endosteum.

⁴*dia* = across; *physis* = growth; originally named for a ridge on the shaft of the tibia

⁵*epi* = upon, above; *physis* = growth

⁶*peri* = around; *oste* = bone

⁷*endo* = within; *oste* = bone

⁸*diplo* = double

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. Name at least five tissues found in a bone.
2. List three or more functions of the skeletal system other than supporting the body and protecting some of the internal organs.
3. Describe the anatomical differences between compact and spongy bone, and their spatial relationship to each other in a long bone and a flat bone.
4. State the anatomical terms for the shaft, head, growth zone, and fibrous covering of a long bone.

7.2 Histology of Osseous Tissue

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. list and describe the cells, fibers, and ground substance of bone tissue;
- b. state the importance of each constituent of bone tissue;

- c. compare the histology of the two types of bone tissue; and
- d. distinguish between the two types of bone marrow.

7.2a Bone Cells

Like any other connective tissue, bone consists of cells, fibers, and ground substance. There are four types of bone cells (**fig. 7.3**):

1. **Osteogenic⁹ cells** are stem cells that develop from embryonic mesenchyme and then give rise to most other bone cell types. They occur in the endosteum and inner layer of the periosteum. They multiply continually, and some go on to become the *osteoblasts* described next. They are the only cells capable of dividing and producing more bone cells.
2. **Osteoblasts¹⁰** are bone-forming cells that synthesize the organic matter of the bone and then promote its mineralization. This bone-building activity is called **osteogenesis**. Osteoblasts form rows in the endosteum and inner layer of the periosteum and resemble a cuboidal epithelium on the bone surface (see **fig. 7.8**). They have abundant mitochondria and endoplasmic reticulum to support their role in osteogenesis. Stress and fractures stimulate accelerated mitosis of osteogenic cells and therefore a rapid rise in the number of osteoblasts, which then reinforce or rebuild the bone.
3. **Osteocytes** are former osteoblasts that have become embedded in the matrix they deposited (see this chapter's opening photo). They number 90% to 95% of the bone cells, and live for decades. They reside in cavities called **lacunae¹¹**, which are interconnected by slender channels called **canaliculi¹²** (CAN-uh-LIC-you-lye). Each osteocyte has delicate cytoplasmic processes called *dendrites* that reach into the canaliculi to contact the processes from neighboring osteocytes, like neighbors reaching out to touch fingertips. Some of them reach out to the nearest blood vessels, and others contact osteoblasts on the bone surface. Neighboring osteocytes are connected by gap junctions where their processes meet, so they can pass nutrients and chemical signals to one another and pass their metabolic wastes to the nearest blood vessel for disposal.

Osteocytes have been found in recent research to be surprisingly versatile cells. Some resorb bone matrix and others deposit it, so they contribute to the homeostatic maintenance of bone density and blood concentrations of calcium and phosphate ions. Perhaps even more importantly, they're strain sensors. When a load is applied to a bone, it produces a flow in the extracellular fluid of the lacunae and canaliculi. This stimulates sensory cilia on the dendrites and induces the cells to secrete signals that regulate bone remodeling—adjustments in bone shape and density to adapt to stress.

⁹*osteo* = bone; *genic* = producing

¹⁰*osteo* = bone; *blast* = form, produce

¹¹*lac* = lake, hollow; *una* = little

¹²*canal* = canal, channel; *icul* = little

FIGURE 7.3 Bone Cells and Their Development. (a) Osteogenic cells give rise to osteoblasts, which deposit matrix around themselves and transform into osteocytes. (b) Bone marrow stem cells fuse to form osteoclasts.

Osteoblasts and osteocytes also are important endocrine cells. One of the hormones they secrete is **osteocalcin**. This is essential to the body's acute stress response—the so-called fight-or-flight reaction. In situations of stress, it inhibits the parasympathetic nervous system and allows the sympathetic nervous system to work unopposed (see section 17.5). In addition, osteocalcin stimulates the pancreas to secrete insulin; it increases the insulin sensitivity of fat cells; it acts on the skeletal muscles to promote energy availability and their capacity for exercise; and it even influences brain development and function and male fertility.

4. **Osteoclasts**¹³ are bone-dissolving cells on the bone surfaces. Their action is called **osteolysis**, the opposite of osteogenesis. They develop from the same bone marrow stem cells as blood cells. Thus, osteogenic cells, osteoblasts, and osteocytes all belong to one cell lineage, but osteoclasts have an independent origin (fig. 7.3). Several stem cells fuse to form each osteoclast, so osteoclasts are unusually large (up to 150 μm) and typically have 3 or 4 nuclei, but sometimes up

to 50. The side of the osteoclast facing the bone surface has a **ruffled border** with many deep infoldings of the plasma membrane that increase surface area and the efficiency of bone resorption. Osteoclasts often reside in pits called **resorption bays** that they etch into the bone surface. Bone remodeling results from the combination of osteogenesis by osteoblasts and osteolysis by osteoclasts.

7.2b The Matrix

The **matrix** of osseous tissue is the stony matter that surrounds the osteocytes and lacunae. It averages, by dry weight, about one-third organic and two-thirds inorganic matter. The organic matter, synthesized by the osteoblasts, includes collagen and various protein-carbohydrate complexes such as glycosaminoglycans, proteoglycans, and glycoproteins (all described in section 2.4c). The inorganic matter is about 85% **hydroxyapatite**, a crystallized calcium phosphate salt $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$; 10% calcium carbonate (CaCO_3); and many inorganic ions. Several foreign elements behave chemically like bone minerals and become incorporated into osseous tissue as contaminants, sometimes with deadly results (see Deeper Insight 7.1).

¹³*osteo* = bone; *clast* = destroy, break down

▶▶▶ APPLY WHAT YOU KNOW

Identify several reasons why an imaginary superhero's skeleton made of steel, though seemingly stronger, would not function as well as natural bone.

The collagen and minerals form a composite material that gives bones a combination of flexibility and strength. The minerals enable a bone to support the weight of the body without sagging. When the bones are deficient in calcium salts, they're soft and bend easily. One way to demonstrate this is to soak a clean dry bone, such as a chicken bone, in vinegar for a few days. As the acid of the vinegar dissolves the minerals, the bone becomes flexible and rubbery. Such mineral deficiency and flexibility are the central problems in the childhood disease *rickets*, in which the soft bones of the lower limbs bend under the body's weight and become permanently deformed (see Deeper Insight 7.3).

The protein component gives bone a degree of flexibility. Without protein, a bone is excessively brittle, as in *osteogenesis imperfecta*, or *brittle bone disease* (see table 7.2 at the end of this chapter). Without collagen, a jogger's bones would shatter under the impact of running. But normally, when a bone bends slightly toward one side, the tensile strength of the collagen fibers on the opposite side holds the bone together and prevents it from snapping like a stick of chalk. Collagen molecules have *sacrificial bonds* that break under stress, protecting a bone from fracture by dissipating some of the shock. The bonds re-form when the collagen is relieved of stress.

Bone varies from place to place in its ratio of minerals to collagen. The middle-ear bones, for example, are about 90% mineral,

giving them the necessary stiffness to efficiently conduct sound vibrations to the inner ear. The limb bones, by contrast, have a higher percentage of collagen, so they can bend slightly under the body's weight. Osseous tissue is thus adapted to different amounts of tension and compression exerted on different parts of the skeleton.

7.2c Compact Bone

The histological study of compact bone usually uses slices that have been dried, cut with a saw, and ground to translucent thinness. This procedure destroys the cells but reveals fine details of the matrix (**fig. 7.4**). Such sections show onionlike **concentric lamellae**—layers of matrix concentrically arranged around a **central (haversian¹⁴) canal** and connected with each other by canaliculi. A central canal and its lamellae constitute an **osteon (haversian system)**—the basic structural unit of compact bone. In longitudinal views and three-dimensional reconstructions, we can see that an osteon is actually a cylinder of tissue surrounding a central canal. Along their length, central canals are joined by transverse or diagonal passages called **perforating canals**. The central and perforating canals are lined with endosteum. Each osteon is separated from its neighbors by a thin *cement line*, which blocks microfractures of the bone from spreading and minimizes the chance of them causing a large-scale fracture.

Collagen fibers “corkscrew” down the matrix of a given lamella in a helical arrangement like the threads of a screw. The helices coil in one direction in one lamella and in the opposite direction in the next lamella (**fig. 7.4b**). This enhances the strength of bone on the same principle as plywood, made of thin layers of wood with the grain running in different directions from one layer to the next. In areas where the bone must resist tension (bending), the helix is loosely coiled like the threads of a wood screw and the fibers are more stretched out on the longitudinal axis of the bone. In weight-bearing areas where resistance to compression is more important, the helix is tightly coiled like the closely spaced threads of a bolt, and the fibers are more nearly transverse.

The skeleton receives about half a liter of blood per minute. Blood vessels, along with nerves, enter the bone tissue through nutrient foramina on the surface. These foramina open into the perforating canals that cross the matrix and feed into the central canals. The innermost osteocytes around each central canal receive nutrients from these blood vessels and pass them along through their gap junctions to neighboring osteocytes. They also receive wastes from their neighbors and convey them to the central canal for removal by the bloodstream. Thus, the dendrites of the osteocytes maintain a two-way flow of nutrients and wastes between the central canal and the outermost cells of the osteon.

Not all of the matrix is organized into osteons. The inner and outer boundaries of dense bone are arranged in *circumferential lamellae* that run parallel to the bone surface. Between osteons, we can find irregular regions called *interstitial lamellae*, the remains of old osteons that broke down as the bone grew and remodeled itself.

DEEPER INSIGHT 7.1 MEDICAL HISTORY

Bone Contamination

When Marie and Pierre Curie and Henri Becquerel received their 1903 Nobel Prize for the discovery of radioactivity (see Deeper Insight 2.1), radiation captured the public imagination. Not for several decades did anyone realize its dangers. For example, factories once employed women to paint luminous numbers on watch and clock dials with radium paint. The women moistened their paint brushes with their tongues to keep them finely pointed and ingested radium in the process. The radium accumulated in their bones and caused many of them to develop a bone cancer called osteosarcoma. History remembers these women as the tragic “radium girls.”

Even more horrific, in the wisdom of hindsight, was a deadly health fad in which people drank “tonics” made of radium-enriched water. One famous enthusiast was the millionaire playboy and championship golfer Eben Byers (1880–1932), who drank several bottles of radium tonic each day and praised its virtues as a wonder drug and aphrodisiac. Like the dial painters, Byers contracted osteosarcoma. By the time of his death, holes had formed in his skull and doctors had removed his entire upper jaw and most of his mandible in an effort to halt the spreading cancer. Byers's bones and teeth were so radioactive they exposed photographic film even in the dark. Brain damage left him unable to speak, but he remained mentally alert to the bitter end. His tragic decline and death shocked the world and helped put an end to the radium tonic fad.

¹⁴Clopton Havers (1650–1702), English anatomist

a: B Christopher/Alamy Stock Photo; c: Jose Luis Calvo/Shutterstock; d: Dennis Strete/McGraw Hill

7.2d Spongy Bone

Spongy bone consists of a lattice of delicate slivers called **spicules**¹⁵ (rods or spines) and **trabeculae**¹⁶ (thin plates or beams) (fig. 7.4a–c; see also fig. 7.21a). Although calcified and hard, it is named for its spongelike appearance. It is covered with endosteum and permeated by spaces filled with bone marrow. The matrix is arranged in lamellae like those of compact bone, but there are few osteons. Central canals aren't needed here because no osteocyte is very far from the marrow. Spongy bone is well designed to impart strength to a bone while adding a minimum of weight. Its trabeculae aren't randomly arranged as they may seem at a glance, but develop along the bone's lines of stress (fig. 7.5). Spongy bone has much more surface area exposed to osteoclast action than compact bone does. Therefore, when osteoclasts resorb bone tissue, it comes mostly from the spongy bone, as we see in osteoporosis (see Deeper Insight 7.4 at the end of this chapter).

7.2e Bone Marrow

Bone marrow is a general term for soft tissue that occupies the marrow cavity of a long bone, the spaces amid the trabeculae of spongy bone, and the larger central canals. There are two kinds of marrow—red and yellow. We can best appreciate their differences by considering how marrow changes over a person's lifetime.

In a child, the marrow cavity of nearly every bone is filled with **red bone marrow (myeloid tissue)**. This is often described as *hematopoietic*¹⁷ tissue (he-MAT-o-poy-ET-ic)—tissue that produces blood cells—but it is actually composed of multiple tissues in a delicate but intricate arrangement, and is properly considered an organ unto itself. Its structure is described in more detail in section 21.1e and figure 21.8.

In adults, most of the red marrow is replaced by fatty **yellow bone marrow**, like the fat at the center of a ham bone. Red marrow is then limited to the skull, vertebrae, ribs, sternum, part of the pelvic (hip) girdle, and the proximal heads of the humerus and femur (fig. 7.6). Yellow bone marrow no longer produces blood, although in the event of severe or chronic anemia, it can transform back into red marrow and resume its hematopoietic function.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- Suppose you had unlabeled electron micrographs of the four kinds of bone cells and their neighboring tissues. Name the four cells and explain how you could visually distinguish each one from the other three.
- Name three organic components of the bone matrix.
- What are the mineral crystals of bone called, and what are they made of?

FIGURE 7.5 Spongy Bone Structure in Relation to Mechanical Stress. In this frontal section of the femur, the trabeculae of spongy bone can be seen oriented along lines of mechanical stress applied by the weight of the body or the pull of a muscle.

B Christopher/Alamy Stock Photo

- Sketch a cross section of an osteon and label its major parts.
- What are the two kinds of bone marrow? What does *hematopoietic tissue* mean? Which type of bone marrow fits this description?

FIGURE 7.6 Adult Distribution of Red and Yellow Bone Marrow.

? What would be the most accessible places to draw red bone marrow from an adult?

¹⁵spic = dart, point; ule = little

¹⁶trabe = beam; cul = little

¹⁷hemato = blood; poietic = forming

7.3 Bone Development

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe two mechanisms of bone formation; and
- explain how mature bone continues to grow and remodel itself.

The formation of bone is called **ossification** (OSS-ih-fih-CAY-shun) or **osteogenesis**. There are two methods of ossification—*intramembranous* and *endochondral*. Both begin with embryonic *mesenchyme* (MEZ-en-kime).

7.3a Intramembranous Ossification

Intramembranous¹⁸ ossification (IN-tra-MEM-bra-nus) produces the flat bones of the skull, most of the clavicle (collarbone), and part of the mandible. Follow its stages in **figure 7.7** as you read the correspondingly numbered descriptions here.

- 1 Mesenchyme first condenses into a soft sheet of tissue permeated with blood vessels—the *membrane* to which *intramembranous* refers. Mesenchymal cells line up along

the blood vessels, become osteoblasts, and secrete a soft collagenous *osteoid*¹⁹ tissue (*prebone*) (**fig. 7.8**) in the direction away from the vessel. Osteoid tissue resembles bone but is not yet calcified.

- 2 Osteoblasts sprout numerous delicate dendrites that penetrate into the osteoid tissue. These promote the deposition of calcium phosphate and other minerals on the collagen fibers of the osteoid tissue, hardening the matrix. Continued osteoid deposition and mineralization squeeze the blood vessels and future bone marrow into narrower and narrower spaces. As they become surrounded by calcified matrix, the osteoblasts become osteocytes—their cell bodies inhabiting the lacunae, and their dendrites reaching out into the canaliculi.
- 3 While the foregoing processes are occurring, more mesenchyme adjacent to the developing bone condenses and forms a fibrous periosteum on each surface. The spongy bone becomes a honeycomb of slender calcified trabeculae.
- 4 At the surfaces, osteoblasts beneath the periosteum deposit layers of bone, fill in the spaces between trabeculae, and create a zone of compact bone on each side, as well as thicken the bone overall. This process gives rise to the sandwichlike structure typical of a flat cranial bone—a layer of spongy bone between two layers of compact bone.

¹⁸intra = within; membran = membrane

¹⁹oste = bone; oid = like, resembling

FIGURE 7.7 Intramembranous Ossification. The figures are drawn to different scales, with the highest magnification and detail at the beginning and backing off for a broader overview at the end of the process.

? With the aid of chapter 8, name at least two specific bones other than the clavicle that would form by this process.

FIGURE 7.8 Intramembranous Ossification in the Fetal Cranium. Note the layers of osteoid tissue, osteoblasts, and fibrous periosteum on both sides of the bone.

Ken Saladin

Intramembranous ossification also plays an important role in the lifelong thickening, strengthening, and remodeling of the long bones discussed next. Throughout the skeleton, it is the method of depositing new tissue on the bone surface even past the age where the bones can no longer grow in length.

7.3b Endochondral Ossification

Endochondral²⁰ ossification (EN-doe-CON-drul) is a process in which a bone develops from a preexisting model composed of hyaline cartilage. It begins around the sixth week of fetal development and continues into a person's 20s. Most bones of the body develop in this way, including the vertebrae, ribs, sternum, scapula, pelvic girdle, and bones of the limbs.

Figure 7.9 shows the following steps in endochondral ossification. This figure uses a metacarpal bone from the palmar region of the hand as an example because of its relative simplicity, having only one *epiphyseal plate* (growth center). Many other bones develop in more complex ways, having an epiphyseal plate at both ends or multiple plates at each end, but the basic process is the same.

- 1 Mesenchyme develops into a body of hyaline cartilage, covered with a fibrous perichondrium, in the location of a future bone. For a time, the perichondrium produces chondrocytes and the cartilage model grows in thickness.
- 2 In a **primary ossification center** near the middle of this cartilage, chondrocytes begin to inflate and die, while the thin walls between them calcify. The perichondrium stops producing chondrocytes and begins producing osteoblasts. These deposit a thin collar of bone around the middle of the cartilage model,

²⁰endo = within; chondr = cartilage

FIGURE 7.9 Stages of Endochondral Ossification. A metacarpal bone of the hand. Light blue represents hyaline cartilage; violet indicates zones of cartilage replacement by bone; and tan indicates calcified bone.

? With the aid of chapter 8, name at least two specific bones that would have two epiphyseal plates (proximal and distal) at stage 5.

reinforcing it like a napkin ring. The former perichondrium is now considered to be a periosteum. As chondrocytes in the middle of the model die, their lacunae merge into a single cavity.

- 3 Blood vessels invade the primary ossification center, delivering blood-borne osteoclasts that digest the calcified tissue. This creates a hollowed-out center called the **primary marrow cavity**. Osteoblasts also arrive and deposit layers of bone lining the cavity, thickening the shaft. As the bony collar under the periosteum thickens and elongates, a wave of cartilage death progresses toward each end of the bone. Osteoclasts in the marrow cavity follow this wave, dissolving calcified cartilage remnants and enlarging the marrow cavity of the diaphysis. The region of transition from cartilage to bone at each end of the primary marrow cavity is called a **metaphysis** (meh-TAFF-ih-sis). Soon, chondrocyte enlargement and death and vascular invasion occur in the epiphysis of the model as well, creating a **secondary ossification center**. In the metacarpal bones, as illustrated in the figure, this occurs in only one epiphysis. In longer bones of the arms, forearms, legs, and thighs, it occurs at both ends.
- 4 The secondary ossification center hollows out by the same process as the diaphysis, generating a **secondary marrow cavity** in the epiphysis. This cavity expands outward from the center in all directions. At the time of birth, the bone typically looks like step 4 in the figure. In bones with two secondary ossification centers, one center lags behind the other, so at birth there is a secondary marrow cavity at one end while chondrocyte growth has just begun at the other. The joints of the limbs are still cartilaginous at birth, much as they are in the 12-week fetus in **figure 7.10**.
- 5 During infancy and childhood, the epiphyses fill with spongy bone. Cartilage is then limited to the articular

FIGURE 7.10 The Fetal Skeleton at 12 Weeks. The red-stained regions are calcified at this age, whereas the elbow, wrist, knee, and ankle joints appear translucent because they are still cartilaginous.

? *Why are the joints of an infant weaker than those of an older child?*

Biophoto Associates/Science Source

cartilage covering each joint surface, and to an **epiphyseal plate** (EP-ih-FIZ-ee-ul), a thin wall of cartilage separating the primary and secondary marrow cavities at one or both ends of the bone. The plate persists through childhood and adolescence and serves as a growth zone for bone elongation.

- 6 By the late teens to early twenties, all remaining cartilage in the epiphyseal plate is generally consumed and the gap between the epiphysis and diaphysis closes. The primary and secondary marrow cavities then unite into a single cavity.

7.3c Bone Growth and Remodeling

Ossification doesn't end at birth, but continues throughout life with the growth and remodeling of bones. Bones grow in two directions: length and width.

Bone Elongation

To understand growth in length, we must return to the epiphyseal plates mentioned earlier (see fig. 7.9, step 5). From infancy through adolescence, an epiphyseal plate is present at one or both ends of a long bone, at the junction between the diaphysis and epiphysis. On X-rays, it appears as a translucent line across the end of a bone, since it is not yet ossified (**fig. 7.11**). The epiphyseal

FIGURE 7.11 X-Ray of a Child's Hand. The cartilaginous epiphyseal plates are evident at the ends of the long bones. Long bones of the hand and fingers develop only one epiphyseal plate. Notice that the wrist is still largely cartilaginous (X-ray translucent). Compare this to the X-ray of an adult hand in figure 8.36c.

Puwadol Jaturawutthichai/Shutterstock

plate is a region of transition from cartilage to bone, and functions as a growth zone where the bones elongate. Growth here is responsible for a person's increase in height.

The epiphyseal plate consists of typical hyaline cartilage in the middle, with a transitional zone on each side where cartilage is being replaced by bone. The transitional zone, facing each marrow cavity, is called the **metaphysis** (meh-TAF-ih-sis). In figure 7.9, step 4, the cartilage is the blue region and each metaphysis is violet. **Figure 7.12** shows the histological structure of the metaphysis and the following steps in the replacement of cartilage by bone.

- ① **Zone of reserve cartilage.** This region, farthest from the marrow cavity, consists of typical hyaline cartilage with resting chondrocytes, not yet showing any sign of transformation into bone.
- ② **Zone of cell proliferation.** A little closer to the marrow cavity, chondrocytes multiply and arrange themselves into longitudinal columns of flattened lacunae.
- ③ **Zone of cell hypertrophy.** Next, the chondrocytes cease to multiply and begin to hypertrophy (enlarge), much like they

do in the primary ossification center of the fetus. The walls of matrix between lacunae become very thin.

- ④ **Zone of calcification.** Minerals are deposited in the matrix between the columns of lacunae and calcify the cartilage. These aren't the permanent mineral deposits of bone, but only a temporary support for the cartilage that would otherwise soon be weakened by the breakdown of the enlarged lacunae.
- ⑤ **Zone of bone deposition.** Within each column, the walls between the lacunae break down and the chondrocytes die. This converts each column into a longitudinal channel (clear spaces in the figure), which is immediately invaded by blood vessels and marrow from the marrow cavity. Osteoblasts line up along the walls of these channels and begin depositing concentric lamellae of matrix, while osteoclasts dissolve the temporarily calcified cartilage.

The process of bone deposition in zone 5 creates a region of spongy bone at the end of the marrow cavity facing the metaphysis. This spongy bone remains for life, although with extensive lifelong

FIGURE 7.12 Zones of the Metaphysis. This micrograph shows the transition from cartilage to bone in the growth zone of a long bone.

? Which two zones in this figure account for a child's growth in height?

Victor Eroschenko

remodeling. But around the perimeter of the marrow cavity, continuing ossification converts this spongy bone to compact bone. Osteoblasts lining the aforementioned channels deposit layer after layer of bone matrix, so the channel grows narrower and narrower. These layers become the concentric lamellae of an osteon. Finally only a slender channel persists, the central canal of a new osteon. Osteoblasts trapped in the matrix become osteocytes.

▶▶▶ APPLY WHAT YOU KNOW

In a given osteon, which lamellae are the oldest—those immediately adjacent to the central canal or those around the perimeter of the osteon? Explain your answer.

How does a child or adolescent grow in height? Chondrocyte multiplication in zone 2 and hypertrophy in zone 3 continually push the zone of reserve cartilage (1) toward the ends of the bone, so the bone elongates. In the lower limbs, this process causes a person to grow in height, while bones of the upper limbs grow proportionately.

Thus, bone elongation is really a result of cartilage growth. Cartilage growth from within, by the multiplication of chondrocytes and deposition of new matrix in the interior, is called **interstitial²¹ growth**. The most common form of dwarfism results from a failure of cartilage growth in the long bones (see Deeper Insight 7.2).

In the late teens to early twenties, all the cartilage of the epiphyseal plate is depleted. The primary and secondary marrow cavities now unite into one cavity. The junctional region where they meet is filled with spongy bone, and the site of the original epiphyseal plate is marked with a line of slightly denser spongy bone called the **epiphyseal line** (see figs. 7.1; 7.5; and 7.9, step 6). Often a delicate ridge on the bone surface marks the location of this line. When the epiphyseal plate is depleted, we say that the epiphyses have “closed” because no gap between the epiphysis and diaphysis is visible on an X-ray. Once the epiphyses have all closed in the lower limbs, a person can grow no taller. The epiphyseal plates close at different ages in different bones and in different regions of the same bone. The processes and rates of elongation and epiphyseal closure are influenced especially by growth hormone and sex steroids (see section 7.4d). The state of closure in various bones of a subadult skeleton is often used in forensic science to estimate an individual’s “bone age” at death.

Bone Widening and Thickening

Bones also continually grow in diameter and thickness. This involves a process called **appositional growth²²**, the deposition of new tissue at the surface. Cartilages grow by both interstitial and appositional growth. In bone, however, osteocytes embedded in calcified matrix have little room to spare for the deposition of more matrix internally. Bone is therefore limited to appositional growth.

Appositional growth occurs by intramembranous ossification at the bone surface. Osteoblasts in the inner layer of periosteum deposit osteoid tissue on the bone surface, calcify it, and become trapped in it as osteocytes—much like the process in figure 7.8. They lay down matrix in layers parallel to the surface, not in cylindrical

osteons like those deeper in the bone. This process produces the surface layers of bone called *circumferential lamellae*, described earlier. As a bone increases in diameter, its marrow cavity also widens. This is achieved by osteoclasts of the endosteum dissolving tissue on the inner bone surface. Thus, flat bones develop by intramembranous ossification alone, whereas long bones develop by a combination of the intramembranous and endochondral methods.

Bone Remodeling

In addition to their growth, bones are continually remodeled throughout life by the absorption of old bone and deposition of new. This process replaces about 10% of the skeletal tissue per year. It releases minerals into the blood for uses elsewhere; reshapes bones in response to use and disuse; and repairs microfractures, preventing them from developing into catastrophic bone failure similar to metal fatigue.

Wolff’s²³ law of bone states that the architecture of a bone is determined by the mechanical stresses placed upon it, and the bone thereby adapts to withstand them. Wolff’s law is a fine example of the complementarity of form and function, showing that the form of a bone is shaped by its functional experience. It is well demonstrated by figure 7.5, in which we see that the trabeculae of spongy bone lie along the lines of stress placed on the femur. Wolff observed that these lines were similar to the ones engineers knew of in mechanical cranes. The effect of stress on bone development is quite evident in elite tennis players, in whom the cortical bone of the racket arm is up to 35% thicker than that of the other arm. Long bones of the limbs are thickest at midshaft, where they are subjected to the greatest stress. Physical therapists use their knowledge of Wolff’s law in designing patient regimens of recovery from fractures and other skeletal abnormalities.

Bone remodeling comes about through the collaborative action of osteoblasts and osteoclasts. If a bone is little used, osteoclasts remove matrix and get rid of unnecessary mass. If a bone is heavily used or stress is consistently applied to a particular region of a bone, osteoblasts deposit new osseous tissue and thicken it. Consequently, the comparatively smooth bones of an infant or toddler develop a variety of surface bumps, ridges, and spines (described in chapter 8) as the child begins to walk. The greater trochanter of the femur, for example (see fig. 7.5), is a massive outgrowth of bone not present at birth. Its development is stimulated by the pull of tendons from several powerful hip muscles as a child begins standing and walking.

On average, bones have a greater density and mass in athletes and people engaged in heavy manual labor than they do in sedentary people. Anthropologists who study ancient skeletal remains use evidence of this sort to help distinguish between members of different social classes, such as distinguishing aristocrats from laborers. Even in studying modern skeletal remains, as in investigating a suspicious death, Wolff’s law comes into play as the bones give evidence of a person’s sex, height, weight, nutritional status, work or exercise habits, ethnic identity, and medical history.

The orderly remodeling of bone depends on a precise balance between deposition and resorption, between osteoblasts and osteoclasts. If one process outpaces the other, or both processes occur

²¹*inter* = between; *stit* = to place, stand

²²*ap* = *ad* = to, near; *posit* = to place

DEEPER INSIGHT 7.2

CLINICAL APPLICATION

Achondroplastic Dwarfism

*Achondroplastic*²⁴ dwarfism (a-con-dro-PLAS-tic) is a condition in which the long bones of the limbs stop growing in childhood, while the growth of other bones is unaffected. As a result, a person has a short stature but a normal-size head and trunk (**fig. 7.13**). As its name implies, achondroplastic dwarfism results from a failure of cartilage growth—specifically, failure of the chondrocytes in zones 2 and 3 of the metaphysis to multiply and enlarge. This is different from *pituitary dwarfism*, in which a deficiency of growth hormone stunts the growth of all of the bones, and a person has short stature but normal proportions throughout the skeletal system.

Achondroplastic dwarfism results from a spontaneous mutation that can arise any time DNA is replicated. Two people of normal height with no family history of dwarfism can therefore have a child with achondroplastic dwarfism. The mutant allele is dominant, so the offspring of a heterozygous achondroplastic dwarf have at least a 50% chance of exhibiting dwarfism, depending on the genotype of the other parent. Persons homozygous for the trait (those who inherit it from both parents) are usually stillborn or die soon after birth.

FIGURE 7.13 Achondroplastic Dwarfism. The student on the right, pictured with her roommate of normal height, is an achondroplastic dwarf with a height of about 122 cm (48 in.). Her parents were of normal height. Note the normal proportion of head to trunk but shortening of the limbs.

Joe DeGrandis/Ken Saladin

too rapidly, various bone deformities, developmental abnormalities, and other disorders occur, such as *osteitis deformans* (Paget disease), *osteogenesis imperfecta* (brittle bone disease), and *osteoporosis* (see table 7.2 and Deeper Insight 7.4).

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

10. Describe the stages of intramembranous ossification. Name a bone that forms in this way.
11. Describe how a cartilage model transforms into a long bone in endochondral ossification.
12. Describe the five zones of a metaphysis and the major distinctions between them.
13. How does Wolff's law explain some of the structural differences between the bones of a young child and the bones of a young adult?

7.4 Physiology of Osseous Tissue

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the processes by which minerals are added to and removed from bone tissue;
- b. discuss the role of the bones in regulating blood calcium and phosphate levels; and
- c. name the main hormones that regulate bone physiology, and describe their effects.

Even after a bone is fully formed, it remains a metabolically active organ with many roles to play. Not only is it involved in its own maintenance, growth, and remodeling, but it also exerts a profound influence on the rest of the body by exchanging minerals with the tissue fluid. Disturbances of calcium homeostasis in the skeleton can disrupt the functioning of other organ systems, especially the nervous and muscular systems. For reasons explained later, such disturbances can even cause death by suffocation.

7.4a Mineral Deposition and Resorption

Mineral deposition (mineralization) is a crystallization process in which calcium, phosphate, and other ions are taken from the blood plasma and deposited in bone tissue, mainly as needlelike crystals of hydroxyapatite. Deposition begins in fetal ossification and continues throughout life.

Osteoblasts begin the process by laying down collagen fibers in a helical pattern along the length of the osteon. These fibers then become encrusted with minerals that harden the matrix. The first few hydroxyapatite crystals to form act as “seed crystals” that attract more calcium and phosphate from solution. The more hydroxyapatite that forms, the more it attracts additional minerals from the tissue fluid, until the matrix is thoroughly calcified.

²⁴a = without; *chondr* = cartilage; *plast* = growth

▶▶▶ APPLY WHAT YOU KNOW

Explain how bone deposition exemplifies the concept of positive feedback described in chapter 1.

Abnormal calcification of tissues, called **ectopic²⁵ ossification**, sometimes occurs in the lungs, brain, eyes, muscles, tendons, arteries, and other organs. One example of this is arteriosclerosis, or “hardening of the arteries,” which results from calcification of the arterial walls. A calcified mass in an otherwise soft organ is called a **calculus²⁶**.

Mineral resorption is the process of dissolving bone. It releases minerals into the blood and makes them available for other uses. Resorption is carried out by osteoclasts. They have surface receptors for calcium and respond to falling levels of calcium in the tissue fluid. Hydrogen pumps in the ruffled border of the osteoclast secrete hydrogen ions into the tissue fluid, and chloride ions follow by electrostatic attraction. The space between the osteoclast and the bone thus becomes filled with concentrated hydrochloric acid with a pH of about 4. The acid dissolves the bone minerals. The osteoclast also secretes an acid-tolerant enzyme (protease) that digests the collagen of the bone matrix.

When orthodontic appliances (braces) are used to reposition teeth, a tooth moves because osteoclasts dissolve bone ahead of the tooth (where the appliance creates greater pressure of the tooth against the bone) and osteoblasts deposit bone in the low-pressure zone behind it.

7.4b Calcium Homeostasis

The adult body contains about 1,100 g of calcium, with 99% of it in the bones. Calcium is needed for much more than bone structure.

It also plays roles in communication among neurons and in muscle contraction, blood clotting, and exocytosis. Calcium is deposited in the skeleton when the supply is ample and withdrawn when needed for these other purposes. The skeleton exchanges about 18% of its calcium with the blood each year.

This exchange is tightly regulated by hormones to maintain a blood calcium concentration of 9.2 to 10.4 mg/dL. This is a narrow margin of safety. A calcium deficiency, called **hypocalcemia²⁷** (HY-po-cal-SEE-me-uh), causes excessive excitability of the nervous system that can result in muscle tremors, spasms, or tetany—inability of the muscles to relax. Tetany of the muscles of the larynx can close off the airway and cause death by suffocation. A calcium excess, called **hypercalcemia²⁸**, makes nerve and muscle cells less excitable than normal. This can be manifested in nervous system depression, emotional disturbances, muscle weakness, sluggish reflexes, and sometimes cardiac arrest.

Hypercalcemia is rare, but hypocalcemia can result from a wide variety of causes including vitamin D deficiency, diarrhea, thyroid tumors, or underactive parathyroid glands. Pregnancy and lactation put women at risk of hypocalcemia because of the calcium demanded by ossification of the fetal skeleton and synthesis of milk.

You can see how critical blood calcium level is, but what causes it to deviate from the norm, and how does the body correct such imbalances? Calcium homeostasis depends on a balance between dietary intake, urinary and fecal losses, and exchanges with the osseous tissue (**fig. 7.14**). It is regulated by three hormones: *calcitriol*, *calcitonin*, and *parathyroid hormone*.

²⁵*ec* = out of; *top* = place

²⁶*calc* = stone; *ulus* = little

²⁷*hypo* = below normal; *calc* = calcium; *emia* = blood condition

²⁸*hyper* = above normal; *calc* = calcium; *emia* = blood condition

FIGURE 7.14 Hormonal Control of Calcium Balance. The central panel represents the blood reservoir of calcium and shows its normal (safe) range. Calcitriol and PTH regulate calcium exchanges between the blood and the small intestine and kidneys (left). Calcitonin, calcitriol, and PTH regulate calcium exchanges between blood and bone (right).

DEEPER INSIGHT 7.3

CLINICAL APPLICATION

Rickets and Osteomalacia

Rickets is a childhood disease in which the bones are soft and deformed as a result of vitamin D and calcium deficiency. It is characterized by fragile bones, bone pain, and frequent fractures; deformity of the chest, pelvis, and spine; and bowed legs (**fig. 7.15**). It is one of the most common childhood diseases of developing countries, but usually preventable by exposure to sunlight. Even 15 minutes per day is usually enough for adequate vitamin D synthesis. Vitamin D can also be obtained from fortified milk and dairy products, eggs, oily fish, and some mushrooms.

Rickets is common in areas wracked with warfare and famine. It also develops in infants who are breast-fed and kept from the sun without receiving supplemental vitamin D. In London during the early 1800s, it occurred in 80% to 90% of children who were kept indoors because of the heavy smog in the air and who were often exploited for long hours of factory work. The United States mandated the addition of vitamin D to milk in 1930 and outlawed child labor in 1937, greatly reducing rickets and other health problems. Yet rickets is increasing again as children spend more time indoors and even because of the increased use of sunscreen. The highest incidence today is in the Mideast, owing to covering of most or all of the body for religious or other cultural reasons.

Osteomalacia is a similar bone-softening, vitamin D deficiency disease of adults. It is especially common in nursing home residents and the homebound elderly. It often begins with lumbar aches and pains and

FIGURE 7.15 Rickets in a Boy of Eastern Kenya.

Jeff Rotman/Alamy Stock Photo

progresses to bone and joint pain, muscle weakness, difficulty walking and stair climbing, loss of height because of vertebral compression, a waddling gait due to spinal deformity, and pathological bone fractures.

Calcitriol

Calcitriol (CAL-sih-TRY-ol) is a form of vitamin D produced by the sequential action of the skin, liver, and kidneys (**fig. 7.16**):

1. Epidermal keratinocytes use ultraviolet radiation from sunlight to convert a steroid, 7-dehydrocholesterol, to *previtamin D₃*. Over another 3 days, the warmth of sunlight on the skin further converts this to vitamin D₃ (*cholecalciferol*), and a transport protein carries this to the bloodstream.
2. The liver adds a hydroxyl group, converting it to *calcidiol*.
3. The kidneys then add another hydroxyl group, converting calcidiol to calcitriol, the most active form of vitamin D.

Calcitriol behaves as a hormone—a blood-borne chemical messenger from one organ to another. It is called a vitamin only because it is added to the diet, mainly in fortified milk, as a safeguard for people who don't get enough sunlight to initiate adequate synthesis in the skin.

The principal function of calcitriol is to raise the blood calcium concentration. It does this in three ways (**fig. 7.14**), especially the first of these:

1. It increases calcium absorption by the small intestine, using mechanisms detailed in chapter 25.
2. It increases calcium resorption from the skeleton. Calcitriol binds to osteoblasts, which then stimulate stem cells to differentiate into osteoclasts. The new osteoclasts liberate calcium and phosphate ions from bone.

3. It weakly promotes the reabsorption of calcium ions by the kidneys, so less calcium is lost in the urine.

Although calcitriol promotes bone resorption, it is also necessary for bone deposition. Without it, calcium and phosphate levels in the blood are too low for normal deposition. The result is a softness of the bones called **rickets** in children and **osteomalacia**²⁹ in adults (see Deeper Insight 7.3).

Calcitonin

Calcitonin is produced by *parafollicular (clear, C) cells* of the thyroid gland (see **fig. 17.9**). It is secreted when the blood calcium concentration rises too high, and it lowers the concentration by two principal mechanisms (**figs. 7.14 and 7.17a**):

1. **Osteoclast inhibition.** Within 15 minutes after it is secreted, calcitonin reduces osteoclast activity by as much as 70%, so osteoclasts liberate less calcium from the skeleton.
2. **Osteoblast stimulation.** Within an hour, calcitonin increases the number and activity of osteoblasts, which deposit calcium into the skeleton.

Calcitonin plays an important role in children but has only a weak effect in most adults. The osteoclasts of children are highly active in skeletal remodeling and release 5 g or more of calcium into the blood each day. By inhibiting this, calcitonin

²⁹oste = bone; malacia = softening

FIGURE 7.17 Negative Feedback Loops in Calcium Homeostasis. (a) The correction of hypercalcemia by calcitonin. (b) The correction of hypocalcemia by parathyroid hormone.

can significantly lower the blood calcium level in children. In adults, however, the osteoclasts release only about 0.8 g of calcium per day. Calcitonin can't change adult blood calcium very much by suppressing this small effect. Calcitonin deficiency isn't known to cause any adult disease. Calcitonin may, however, help to maintain bone density in pregnant and lactating women.

Parathyroid Hormone

Parathyroid hormone (PTH) is secreted by the parathyroid glands, which adhere to the posterior surface of the thyroid gland. These glands release PTH when blood calcium is low. A mere 1% drop in the calcium level doubles PTH secretion. PTH raises the calcium level by four mechanisms (figs. 7.14 and 7.17b):

1. It binds to receptors on the osteoblasts, which in turn stimulate the osteoclast population and promote bone resorption.
2. It promotes calcium reabsorption by the kidneys, so less calcium is lost in the urine.
3. It promotes the final step of calcitriol synthesis in the kidneys, thus enhancing the calcium-raising effect of calcitriol.
4. It inhibits collagen synthesis by osteoblasts, thus inhibiting bone deposition.

7.4c Phosphate Homeostasis

The average adult has 500 to 800 g of phosphorus, of which 85% to 90% is in the bones. Phosphate is required not only for bone strength but also as a component of DNA, RNA, ATP, phospholipids, and other compounds. Plasma phosphorus concentration ranges from 3.5 to 4.0 mg/dL. Its level is not as tightly regulated as calcium. Nor, apparently, does it need to be; changes in plasma phosphate level are not associated with any immediate functional disorder. Calcitriol raises the phosphate level by promoting its absorption from the diet by the small intestine. This makes sense, because one effect of calcitriol is to promote bone deposition, and that requires both calcium and phosphate. Parathyroid hormone, on the other hand, lowers the blood phosphate level by promoting its urinary excretion.

▶▶▶ APPLY WHAT YOU KNOW

While raising the blood calcium level, PTH lowers the phosphate level. Explain why this is important for achieving the purpose of PTH.

7.4d Other Factors Affecting Bone

At least 20 more hormones, growth factors, and vitamins affect osseous tissue in complex ways that are still not well understood (**table 7.1**). Bone growth is especially rapid in puberty

TABLE 7.1 Agents Affecting Calcium and Bone Metabolism

Name	Effect
Hormones	
Calcitonin	Promotes mineralization and lowers blood Ca^{2+} concentration in children, but usually has little effect in adults; may prevent bone loss in pregnant and lactating women
Calcitriol (vitamin D)	Promotes intestinal absorption of Ca^{2+} and phosphate; reduces urinary excretion of both; promotes both resorption and mineralization; stimulates osteoclast activity
Cortisol	Inhibits osteoclast activity, but if secreted in excess (Cushing disease), can cause osteoporosis by reducing bone deposition (inhibiting cell division and protein synthesis), inhibiting growth hormone secretion, and stimulating osteoclasts to resorb bone
Estrogen	Stimulates osteoblasts and adolescent growth; prevents osteoporosis
Growth hormone	Stimulates bone elongation and cartilage proliferation at epiphyseal plate; increases urinary excretion of Ca^{2+} but also increases intestinal Ca^{2+} absorption, which compensates for the loss
Insulin	Stimulates bone formation; significant bone loss occurs in untreated diabetes mellitus
Parathyroid hormone	Indirectly activates osteoclasts, which resorb bone and raise blood Ca^{2+} concentration; inhibits urinary Ca^{2+} excretion; promotes calcitriol synthesis
Testosterone	Stimulates osteoblasts and promotes protein synthesis, thus promoting adolescent growth and epiphyseal closure
Thyroid hormone	Essential to bone growth; enhances synthesis and effects of growth hormone, but excesses can cause hypercalcemia, increased Ca^{2+} excretion in urine, and osteoporosis
Growth Factors	At least 12 hormonelike substances produced in bone itself that stimulate neighboring bone cells, promote collagen synthesis, stimulate epiphyseal growth, and produce many other effects
Vitamins	
Vitamin A	Promotes glycosaminoglycan (chondroitin sulfate) synthesis
Vitamin C (ascorbic acid)	Required for collagen synthesis, bone growth, and fracture repair
Vitamin D	Normally functions as a hormone (see calcitriol)

and adolescence, when surges of growth hormone, estrogen, and testosterone promote ossification. These hormones stimulate rapid multiplication of osteogenic cells, matrix deposition by osteoblasts, and multiplication and hypertrophy of the chondrocytes in the metaphyses. Adolescent girls grow faster than boys and attain their full height earlier, not only because they begin puberty earlier but also because estrogen has a stronger effect than testosterone. Since males grow for a longer time, however, they usually grow taller. Sex steroids eventually deplete the cartilage of the epiphyseal plates, bring about closure of the epiphyses, and put an end to one's growth in height. A deficiency or excess of these steroids can therefore cause abnormalities ranging from stunted growth to exceptionally tall stature. The use of anabolic steroids by adolescent athletes can cause premature closure and result in abnormally short adult stature (see Deeper Insight 2.6). The excessive consumption of cola (more than three 12-ounce servings per day) is associated with loss of bone density in women, but not in men. The effect is thought to be due to the phosphoric acid in cola, which binds intestinal calcium and interferes with its absorption. Other soft drinks don't contain phosphoric acid or affect bone density.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

14. Describe the role of collagen and seed crystals in bone mineralization.
15. Why is it important to regulate blood calcium concentration within such a narrow range?
16. What effect does calcitonin have on blood calcium concentration, and how does it produce this effect? Answer the same questions for parathyroid hormone.
17. How is vitamin D synthesized, and what effect does it have on blood calcium concentration?

7.5 Bone Disorders

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name and describe several bone diseases;
- b. name and describe the types of fractures;
- c. explain how a fracture is repaired; and
- d. discuss some clinical treatments for fractures and other skeletal disorders.

Most people probably give little thought to their skeletal systems unless they break a bone. This section describes bone fractures, their healing, and their treatment, followed by a summary of other bone diseases. Bone disorders are among the concerns of

orthopedics,³⁰ a branch of medicine that originated as the treatment of skeletal deformities in children. It is now much more extensive and deals with the prevention and correction of injuries and disorders of the bones, joints, and muscles at all ages. It includes the design of artificial joints and limbs and the treatment of athletic injuries.

7.5a Fractures and Their Repair

There are multiple ways of classifying bone fractures. A **stress fracture** is a break caused by abnormal trauma to a bone, such as fractures incurred in falls, athletics, auto accidents, and military combat. A **pathological fracture** is a break in a bone weakened by some other disease, such as bone cancer or osteoporosis, usually caused by a stress that wouldn't normally fracture a bone. Fractures are also classified according to the direction of the fracture line, whether the skin is broken, and whether a bone is merely cracked or broken into separate pieces. For example, a *nondisplaced* fracture is one in which the bone pieces remain in proper anatomical alignment, whereas a *displaced* fracture is one in which at least one piece is shifted out of alignment with the other (**fig. 7.18a, b**). A *comminuted* fracture is one in which a bone is broken into three or more pieces (**fig. 7.18c**). A *greenstick* fracture is one in which the bone is incompletely broken on one side but merely bent on the opposite side (**fig. 7.18d**), the way a green twig breaks only partially and not into separate pieces. Several other types of fractures are routinely taught in clinical and first aid courses.

The Healing of Fractures

An uncomplicated fracture heals in about 8 to 12 weeks, but complex fractures take longer and all fractures heal more slowly in older people. The healing process occurs in the following stages (**fig. 7.19**):

- 1 **Formation of hematoma and granulation tissue.** A bone fracture severs blood vessels of the bone and periosteum, causing bleeding and the formation of a blood clot (*fracture hematoma*). Blood capillaries soon grow into the clot, while fibroblasts, macrophages, osteoclasts, and osteogenic cells invade the tissue from both the periosteal and medullary sides of the fracture. Osteogenic cells become very abundant within 48 hours of the injury. All of this capillary and cellular invasion converts the blood clot to a soft fibrous mass called **granulation tissue**.
- 2 **Formation of a soft callus.**³¹ Fibroblasts deposit collagen in the granulation tissue, while some osteogenic cells become chondroblasts and produce patches of fibrocartilage called the **soft callus**.

³⁰*ortho* = straight; *ped* = child, foot

³¹*call* = hard, tough

FIGURE 7.18 X-Rays of Representative Fracture Types.

a: ChooChin/Getty Images; b: Howard Kingsnorth/The Image Bank/Getty Images; c: Ken Saladin/Emory M. Saladin; d: Biophoto Associates/Science Source

- 3 **Conversion to hard callus.** Other osteogenic cells differentiate into osteoblasts, which produce a bony collar called the **hard callus** around the fracture. The hard callus is cemented to dead bone around the injury site and acts as a temporary splint to join the broken ends or bone fragments together. It takes about 4 to 6 weeks for a hard callus to form. During this period, it is important that a broken bone be immobilized to prevent reinjury.
- 4 **Remodeling.** The hard callus persists for 3 to 4 months. Meanwhile, osteoclasts dissolve small fragments of broken bone, and osteoblasts deposit spongy bone to bridge the gap between the broken ends. This spongy bone gradually fills in to become compact bone, in a manner similar to intramembranous ossification. Usually the fracture leaves a slight thickening of the bone visible by X-ray; such thickenings may serve as forensic evidence of child abuse. In some cases, however, healing is so complete that no trace of the fracture can be found.

The Treatment of Fractures

Most fractures are set by **closed reduction**, a procedure in which the bone fragments are manipulated into their normal positions without surgery. **Open reduction and internal fixation (ORIF)** involves surgically exposing the fractured bone and using plates, screws, or pins to realign the fragments (**fig. 7.20**). Hip fractures are usually pinned, and early ambulation (walking) is encouraged because it promotes blood circulation and healing. Fractures that take longer than 2 months to heal may be treated with electrical stimulation, which accelerates repair by suppressing the effects of parathyroid hormone.

7.5b Other Bone Disorders

Several additional bone disorders are summarized in **table 7.2**. The most common bone disease, osteoporosis, receives special

FIGURE 7.19 The Healing of a Bone Fracture.

FIGURE 7.20 Open Reduction and Internal Fixation (ORIF) of a Compound Fracture of the Tibial Plateau.

Kenneth S. Saladin

consideration in Deeper Insight 7.4. The effects of aging on the skeletal system are described in chapter 29.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- 18. Name and describe four types of bone fractures.
- 19. Why would osteomyelitis be more likely to occur in an open fracture than in a closed fracture?
- 20. What is a callus? How does it contribute to fracture repair?

TABLE 7.2 Bone Diseases	
Osteitis deformans (Paget ³² disease)	Excessive proliferation of osteoclasts and resorption of excess bone, with osteoblasts attempting to compensate by depositing extra bone. This results in rapid, disorderly bone remodeling and weak, deformed bones. Osteitis deformans usually passes unnoticed, but in some cases it causes pain, disfiguration, and fractures. It is most common in males over the age of 50.
Osteomyelitis ³³	Inflammation of osseous tissue and bone marrow as a result of bacterial infection. This disease was often fatal before the discovery of antibiotics and is still very difficult to treat.
Osteogenesis imperfecta (brittle bone disease)	A defect in collagen deposition that renders bones exceptionally brittle, resulting in fractures present at birth or occurring with extraordinary frequency during childhood; also causing tooth deformity, and hearing loss due to deformity of middle-ear bones. Results from mutation of any of several collagen genes.
Osteosarcoma ³⁴ (osteogenic sarcoma)	The most common and deadly form of bone cancer. It occurs most often in the tibia, femur, and humerus of males between the ages of 10 and 25. In 10% of cases, it metastasizes to the lungs or other organs; if untreated, death typically occurs within 1 year.
You can find other skeletal system disorders described in the following places:	
Achondroplastic dwarfism in Deeper Insight 7.2; ectopic ossification in section 7.4; rickets and osteomalacia in Deeper Insight 7.3; bone fractures (in general) in section 7.5a; osteoporosis in Deeper Insight 7.4; mastoiditis in section 8.2a; herniated discs in Deeper Insight 8.3; abnormal spinal curvatures in Deeper Insight 8.3; fractured clavicle in section 8.4a; fallen arches in section 8.5b; arthritis in Deeper Insight 9.5; and cleft palate in Deeper Insight 29.4.

³³oste = bone; myel = marrow; itis = inflammation
³⁴oste = bone; sarc = flesh; oma = tumor

DEEPER INSIGHT 7.4

CLINICAL APPLICATION

Osteopenia and Osteoporosis

Loss of bone density is one of the most common concerns of aging. Osteocytes live for decades, but eventually they die and leave empty lacunae. For this and other reasons, beginning around age 40, many of us lose bone by resorption faster than it can be replaced. Early on, this causes no noticeable symptoms, but it can progress to a measurable decline in bone density called **osteopenia**.³⁵ Spongy bone is affected the most, because it has the greatest surface area exposed to the bone-dissolving osteoclasts (**fig. 7.21a**). The risk of fractures rises as density declines.

To some extent, this is associated with risk factors we can't control—sex (women are more affected than men), body build (affecting people of small, light frames more than heavier people), ancestry (women of Asian and White European origin are especially vulnerable; Black women of African ancestry less so), and of course, age itself. There are other risk factors we can control—a sedentary lifestyle, inadequate weight-bearing exercise (even walking), dietary habits (inaequate intake of calcium, vitamin D, and protein), smoking, and excessive alcohol consumption.

For many, osteopenia quietly advances to the more serious condition, **osteoporosis**.³⁶ The bones are then so eroded that one can suffer fractures from stresses as slight as sitting down too quickly, and of course from falls or blows that wouldn't faze a healthier skeleton. Fractures of the hip, wrist, and spine are especially common. Among the elderly, slowly healing hip fractures can impose prolonged immobility and lead to life-threatening complications such as pneumonia. Survivors often face long, costly recovery. Osteoporosis commonly causes spinal deformity because the mere weight of the upper body bears down on the vertebrae and collapses them (**fig. 7.21b**). The spine develops an exaggerated thoracic curvature called *hyperkyphosis*, impairing one's mobility and independence (**fig. 7.21c**).

³⁵ *osteo* = bone; *penia* = deficiency, lack

³⁶ *osteo* = bone; *por* = holes, pores; *osis* = condition

About 30% of U.S. women suffer fractures due to osteoporosis at some point in their lives. Compared to men, women average less initial bone mass and begin to lose it at an earlier age. Since estrogen supports bone deposition, the risk of osteoporosis rises sharply after menopause, when the ovaries cease to produce it. By age 70, the average White or Asian woman has lost 30% of her bone mass, and some as much as 50%. Osteopenia and osteoporosis are surprisingly common, however, in young female runners, dancers, and gymnasts in spite of their vigorous exercise. Some have such a low percentage of body fat that they stop ovulating, and without developing follicles, their ovaries secrete low levels of estrogen. About 20% of osteoporosis sufferers are men. Loss of bone density (along with muscle mass) is a significant health problem even for astronauts on prolonged space missions, where their bones are subjected to little of the stress that normally maintains bone and muscle mass. This is why exercise equipment is standard on space stations.

The gold standard for assessment of bone density is *bone densitometry*, or the *DEXA scan* (*dual energy X-ray absorptiometry*). This is a very sensitive technique that scans the spine and hips with low-dose X-rays. DEXA has enabled earlier diagnosis and more effective treatment of osteoporosis. However, the severity of osteoporosis depends not on bone density alone, but also on the degree of connectivity between the spongy bone trabeculae, which is lost as trabeculae deteriorate. No diagnostic method yet available can detect or assess this.

Treatment strategies for osteoporosis revolve around drugs to stimulate bone deposition or slow the rate of resorption. This is an intensive area of pharmaceutical research and new drugs are brought to market often. As with so many other disorders, prevention is far preferable to treatment. Prevention is best begun in the young, bone-forming years of one's teens to 30s, but continued even into old age. It includes weight-bearing exercise and avoidance of the aforesaid elective risk factors. For the elderly, such exercises as dancing, stair climbing, walking, and running can be effective and pleasurable ways of minimizing the risk or severity of osteoporosis.

SYSTEM CONNECTIONS

Effects of the **SKELETAL SYSTEM** on Other Organ Systems

INTEGUMENTARY SYSTEM

Bones lying close to the body surface support and shape the skin.

MUSCULAR SYSTEM

Bones are the attachment sites for most skeletal muscles and provide leverage for muscle action; calcium homeostasis, important for muscle contraction, is achieved partly through a balance between bone deposition and resorption.

NERVOUS SYSTEM

The cranium and vertebral column protect the brain and spinal cord; osseous tissue provides the calcium homeostasis needed for nerve function.

ENDOCRINE SYSTEM

Bones protect endocrine glands in the head, thorax, and pelvis; bones secrete the hormone osteocalcin, which promotes insulin action; hormone secretion depends on calcium homeostasis.

CIRCULATORY SYSTEM

Bone marrow forms blood cells and platelets; osseous tissue provides the calcium homeostasis needed for cardiac function and blood clotting.

LYMPHOID AND IMMUNE SYSTEMS

White blood cells produced in the bone marrow carry out the body's immune functions.

RESPIRATORY SYSTEM

Ventilation of the lungs is achieved by musculoskeletal actions of the thoracic cage; the thoracic cage protects the delicate lungs from trauma; bones support and shape the nasal cavity.

URINARY SYSTEM

The thoracic cage partially protects the kidneys, and the pelvic girdle protects the lower urinary tract.

DIGESTIVE SYSTEM

Osseous tissue interacts with the digestive system in maintaining calcium homeostasis; the thoracic cage and pelvic girdle protect portions of the digestive tract; musculoskeletal movements are necessary for chewing.

REPRODUCTIVE SYSTEM

The pelvic girdle protects the internal reproductive organs; childbirth is adapted to the anatomy of the female pelvic girdle; ligaments anchor the penis, clitoris, uterus, and ovaries to the pelvic girdle.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

7.1 Tissues and Organs of the Skeletal System

1. The branch of medicine and biology that deals with the skeleton and bone tissue
2. Organs and tissues that constitute the skeletal system
3. Functions of the skeletal system
4. Which primary tissue category includes bone, and how bone differs from other tissues in that category
5. The relationship of compact bone, spongy bone, and the marrow cavity in the anatomy of a long bone
6. Other anatomical features of a long bone including the diaphysis, epiphysis, epiphyseal plate, articular cartilage, periosteum, and endosteum
7. Structure of a typical flat bone

7.2 Histology of Osseous Tissue

1. The four cell types in bone tissue; their functions, origins, and locations in the tissue
2. Organic and inorganic components of the bone matrix; their respective contributions to bone strength; and the significance of the helical arrangement of collagen fibers in bone
3. Osteon structure and the relationship of osteonic bone to interstitial and circumferential lamellae

4. The route by which nerves and blood vessels penetrate throughout a bone
5. Comparisons of the histology of spongy bone with that of compact bone; where spongy bone is found; and why bones are not composed solely of compact bone
6. Location and functions of the bone marrow; the composition and childhood versus adult distribution of the two types of marrow

7.3 Bone Development

1. Stages of intramembranous ossification; some bones that form in this way; and how far this process has progressed by birth
2. The same points concerning endochondral ossification
3. Histology, cell transformations, and tissue zones of the metaphysis; which zones and processes account for a child's or adolescent's growth in height
4. How stresses on bones remodel them throughout life; the difference between interstitial and appositional growth

7.4 Physiology of Osseous Tissue

1. The purpose and process of mineralization of osseous tissue, and the identity of the cells that carry it out
2. The purpose and process of bone resorption, and the identity of the cells and cell secretions that carry it out
3. Functions of calcium in the body; the normal range of blood calcium concentration;

and causes and consequences of hypocalcemia and hypercalcemia

4. The role of the skeleton as a calcium reservoir in regulating blood calcium levels
5. How calcitriol is synthesized and the mechanisms by which it supports or raises blood calcium level
6. The source of calcitonin and how it corrects hypercalcemia
7. The source of parathyroid hormone and multiple mechanisms by which it corrects hypocalcemia
8. Two forms of phosphate ions in the blood; the bodily functions of phosphate; and how calcitriol and parathyroid hormone affect blood phosphate levels
9. Effects of dietary vitamins A, C, and D on bone metabolism
10. Effects of cortisol, estrogen, testosterone, growth hormone, insulin, and thyroid hormone on bone metabolism

7.5 Bone Disorders

1. The difference between a stress fracture and a pathological fracture; stages in the healing of a fractured bone; and approaches to the clinical treatment of fractures
2. Causes of osteoporosis; its risk factors, pathological effects, diagnosis, treatment, and prevention

► Testing Your Recall

Answers in Appendix A

1. Which cells have a ruffled border and secrete hydrochloric acid?
 - a. C cells
 - b. osteocytes
 - c. osteogenic cells
 - d. osteoblasts
 - e. osteoclasts
2. The marrow cavity of an adult bone may contain
 - a. myeloid tissue.
 - b. hyaline cartilage.
 - c. periosteum.
 - d. osteocytes.
 - e. articular cartilages.
3. The spurt of growth in puberty results from cell proliferation and hypertrophy in
 - a. the epiphysis.
 - b. the epiphyseal line.
 - c. compact bone.
 - d. the epiphyseal plate.
 - e. spongy bone.
4. Osteoclasts are most closely related, by common descent, to
 - a. osteoprogenitor cells.
 - b. osteogenic cells.
 - c. blood cells.
 - d. fibroblasts.
 - e. osteoblasts.
5. The walls between cartilage lacunae break down in the zone of
 - a. cell proliferation.
 - b. calcification.
 - c. reserve cartilage.
 - d. bone deposition.
 - e. cell hypertrophy.
6. Which of these is *not* an effect of PTH?
 - a. rise in blood phosphate level
 - b. reduction of calcium excretion
 - c. increased intestinal calcium absorption
 - d. increased number of osteoclasts
 - e. increased calcitriol synthesis

STUDY GUIDE

7. A child jumps to the ground from the top of a playground “jungle gym.” His leg bones don’t shatter mainly because they contain
 - a. an abundance of glycosaminoglycans.
 - b. young, resilient osteocytes.
 - c. an abundance of calcium phosphate.
 - d. collagen fibers.
 - e. hydroxyapatite crystals.
8. One long bone meets another at its
 - a. diaphysis.
 - b. epiphyseal plate.
 - c. periosteum.
 - d. metaphysis.
 - e. epiphysis.
9. Calcitriol is made from
 - a. calcitonin.
 - b. 7-dehydrocholesterol.
 - c. hydroxyapatite.
 - d. estrogen.
 - e. PTH.
10. One sign of osteoporosis is
 - a. osteosarcoma.
 - b. osteomalacia.
 - c. osteomyelitis.
 - d. a spontaneous wrist fracture.
 - e. hypocalcemia.
11. Calcium phosphate crystallizes in bone as a mineral called _____.
12. Osteocytes contact each other through channels called _____ in the bone matrix.
13. A bone increases in diameter only by _____ growth, the addition of new surface lamellae.
14. Seed crystals of hydroxyapatite form only when the levels of calcium and phosphate in the tissue fluid exceed the _____.
15. A calcium deficiency called _____ can cause death by suffocation.
16. _____ are cells that secrete collagen and stimulate calcium phosphate deposition.
17. The most active form of vitamin D, produced mainly by the kidneys, is _____.
18. The most common bone disease is _____.
19. The transitional region between epiphyseal cartilage and the primary marrow cavity of a young bone is called the _____.
20. A pregnant, poorly nourished woman may suffer a softening of the bones called _____.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|-----------|-------------|------------|
| 1. calc- | 3. -malacia | 7. osteo- |
| 2. -clast | 4. myelo- | 8. -physis |
| | 5. ortho- | 9. spic- |
| | 6. osse- | 10. topo- |

► What’s Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. The flat cranial bones are composed of compact bone only, with no spongy bone.
2. In endochondral ossification, bone tissue is formed by the calcification of preexisting cartilage.
3. Fractures are the most common bone disorder.
4. The growth zone of the long bones of adolescents is the articular cartilage.
5. Osteoclasts develop from osteoblasts.
6. Osteoblasts are multipotent stem cells.
7. The protein of the bone matrix is called hydroxyapatite.
8. Osteocytes are nourished by blood capillaries in the canaliculi of the osteons.
9. Vitamin D promotes bone deposition, not resorption.
10. Parathyroid hormone stimulates bone deposition by osteoblasts.

► Testing Your Comprehension

1. Most osteocytes of an osteon are far removed from blood vessels, but still receive blood-borne nutrients. Explain how this is possible.
2. Charlie, a 50-year-old business executive, decides to get more exercise and takes up hiking. Within 2 years, Charlie is spending many weekends hiking with a heavy backpack and camping in the mountains. Explain what changes in Charlie’s anatomy could be predicted from Wolff’s law of bone.
3. How does the regulation of blood calcium concentration exemplify negative feedback and homeostasis?
4. Describe how the arrangement of trabeculae in spongy bone demonstrates the unity of form and function.
5. Identify two bone diseases you would expect to see if the epidermis were a completely effective barrier to UV radiation and a person took no dietary supplements to compensate for this. Explain your answer.

8.4 Evolutionary Medicine: Skeletal Adaptations for Bipedalism

Module 5: Skeletal System

BRUSHING UP

- Anatomical descriptions of the skeletal system depend heavily on the directional terminology introduced in atlas A, table A.1.
- Understanding skeletal anatomy also depends on knowledge of the terms for body regions and cavities described in atlas A.

Knowledge of skeletal anatomy will be useful as you study later chapters. It provides a point of reference for learning the gross anatomy of other organ systems because many organs are named for their relationships to nearby bones. The subclavian artery and vein, for example, lie adjacent to the clavicle; the temporalis muscle is attached to the temporal bone; the ulnar nerve and radial artery travel beside the ulna and radius of the forearm; and the frontal, parietal, temporal, and occipital lobes of the brain are named for adjacent bones of the cranium. Understanding how the muscles produce body movements also depends on knowledge of skeletal anatomy. Additionally, the positions, shapes, and processes of bones can serve as landmarks for clinicians in determining where to give an injection or record a pulse, what to look for in an X-ray, and how to perform physical therapy and other clinical procedures.

8.1 Overview of the Skeleton

Expected Learning Outcomes

When you have completed this section, you should be able to

- define the two subdivisions of the skeleton;
- state the approximate number of bones in the adult body;
- explain why the number of bones in the skeleton varies with age and from one person to another; and
- define several terms that denote surface features of bones.

The skeleton (**fig. 8.1**) is divided into two regions: the axial and appendicular skeleton. The **axial skeleton**, which forms the central supporting axis of the body, includes the skull, auditory ossicles (middle-ear bones), hyoid bone, vertebral column, and thoracic cage (ribs and sternum). The **appendicular skeleton** includes the bones of the upper limb and pectoral girdle and the bones of the lower limb and pelvic girdle.

8.1a Bones of the Skeletal System

It is often stated that there are 206 bones in the skeleton, but this is only a typical adult count, not an invariable number. At birth there are about 270, and even more bones form during childhood. With age, however, the number decreases as separate bones gradually fuse. For example, each side of a child’s pelvic girdle has three bones—the *ilium*, *ischium*, and *pubis*—but in adults, these are fused into a single *hip bone* on each side. The

fusion of several bones, completed by late adolescence to the mid-20s, brings about the average adult number of 206. These bones are listed in **table 8.1**.

This number varies even among adults. One reason is the development of **sesamoid**¹ bones—bones that form within

¹*sesam* = sesame seed; *oid* = resembling

TABLE 8.1 Bones of the Adult Skeletal System

some tendons in response to strain. The patella (kneecap) is the largest of these; most of the others are small, rounded bones in such locations as the hands and feet (see fig. 8.36c).

Another reason for adult variation is that some people have extra bones in the skull called **sutural bones** (SOO-chur-ul) (see fig. 8.8).

8.1b Anatomical Features of Bones

Bones exhibit a variety of ridges, spines, bumps, depressions, canals, pores, slits, cavities, and articular surfaces. It is important to know the names of these *bone markings* because later descriptions of joints, muscle attachments, and the routes traveled by nerves and blood vessels are based on this terminology. Terms for the most common bone features are listed in **table 8.2**, and several are illustrated in **figure 8.2**.

TABLE 8.2 Anatomical Features (Markings) of Bones	
Term	Description and Example
Articulations (Joint Surfaces)	
Condyle	A rounded knob that articulates with another bone (occipital condyles of the skull)
Facet	A smooth, flat, slightly concave or convex articular surface (articular facets of the vertebrae)
Head	The prominent expanded end of a bone, sometimes rounded (head of the femur)
Extensions and Projections	
Crest	A narrow ridge (iliac crest of the pelvis)
Epicondyle	An expanded region proximal to a condyle (medial epicondyle of the femur)
Line	A slightly raised, elongated ridge (nuchal lines of the skull)
Process	Any bony prominence (mastoid process of the skull)
Protuberance	A bony outgrowth or protruding part (mental protuberance of the chin)
Ramus	A branch or arm (ramus of mandible)
Spine	A sharp, slender, or narrow process (mental spines of the mandible)
Trochanter	Two massive processes unique to the femur
Tubercle	A small, rounded process (greater tubercle of the humerus)
Tuberosity	A rough elevated surface (tibial tuberosity)
Depressions	
Alveolus	A pit or socket (tooth socket)
Fossa	A shallow, broad, or elongated basin (mandibular fossa)
Fovea	A small pit (fovea capitis of the femur)
Sulcus	A groove for a tendon, nerve, or blood vessel (intertubercular sulcus of the humerus)
Passages and Cavities	
Canal	A tubular passage or tunnel in a bone (auditory canal of the skull)
Fissure	A slit through a bone (orbital fissures behind the eye)
Foramen	A hole through a bone, usually round (foramen magnum of the skull)
Sinus	An air-filled space in a bone (frontal sinus of the forehead)

(a) Skull (lateral view)

(b) Scapula (posterior view)

(c) Femur (posterior view) (d) Humerus (anterior view)

FIGURE 8.2 Anatomical Features of Bones. (a) Skull, lateral view. (b) Scapula, posterior view. (c) Femur, posterior view. (d) Humerus, anterior view. Most of these features also occur on many other bones of the body.

You will probably study both **articulated** skeletons (dried bones held together by wires and rods to show their spatial relationships to each other) and **disarticulated** bones (bones taken apart so their surface features can be studied in more detail). As you study this chapter, also use yourself as a model. You can easily palpate (feel) many of the bones and some of their details through the skin. Rotate your forearm; cross your legs; palpate your skull, knee, elbow, and wrist; and think about what is happening beneath the surface or what you can feel through the skin. You will gain the most from this chapter (and indeed, the entire book) if you are conscious of your own body in relation to what you are studying.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. Name the major components of the axial skeleton. Name those of the appendicular skeleton.
2. Explain why an adult does not have as many bones as a child does. Explain why one adult may have more bones than another.
3. Briefly describe each of the following bone features: a condyle, crest, tubercle, fossa, sulcus, and foramen.

8.2 The Skull

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. distinguish between cranial and facial bones;
- b. name the bones of the skull and their anatomical features;

- c. identify the cavities in the skull and in some of its individual bones;
- d. name the principal sutures that join the bones of the skull;
- e. describe some bones that are closely associated with the skull; and
- f. describe the development of the skull from infancy through childhood.

The skull is the most complex part of the skeleton. Although it may seem to consist only of the mandible (lower jaw) and “the rest,” it is composed of 22 bones and sometimes more. **Figures 8.3 through 8.5** present an overview of its general anatomy; its individual bones are described in sections 8.2a and b.

The skull contains several prominent cavities (**fig. 8.6**). The largest, with an adult volume of about 1,350 mL, is the **cranial cavity**, which encloses the brain. Other cavities include the **orbits** (eye sockets), **nasal cavity**, **oral (buccal) cavity**, **middle- and inner-ear cavities**, and **paranasal sinuses**. These sinuses are named for the bones in which they occur—the **frontal**, **sphenoidal**, **ethmoidal**, and **maxillary sinuses** (**fig. 8.7**). They are connected with the nasal cavity, lined by mucous membranes, and filled with air. They lighten the anterior portion of the skull and act as chambers that add resonance to the voice. The latter effect can be sensed in the way your voice changes when you have a cold and mucus obstructs the travel of sound into the sinuses and back.

Most bones of the skull are connected by immovable joints called **sutures** (SOO-chers), visible as seams on the surface. These are important landmarks in the descriptions that follow. Most are labeled in the following figures; some are best seen in the roof of the cranial cavity, called the **calvaria**² (**fig. 8.8**).

Bones of the skull have numerous **foramina**—singular, **foramen** (fo-RAY-men)—holes that allow passage for nerves and blood vessels leading to and from the brain. Several major foramina are summarized in **table 8.3**. Some of these will be most relevant when you study later chapters describing the cranial nerves and blood vessels that pass through them.

²calvar = bald, skull

TABLE 8.3 Foramina of the Skull and the Nerves and Blood Vessels Transmitted Through Them

Bones and Their Foramina	Structures Transmitted
Frontal Bone	
Supraorbital foramen or notch	Supraorbital nerve, artery, and vein
Temporal Bone	
Carotid canal	Internal carotid artery
External acoustic meatus	Sound waves to eardrum
Internal acoustic meatus	Vestibulocochlear nerve
Jugular foramen	Internal jugular vein; glossopharyngeal, vagus, and accessory nerves
Occipital Bone	
Foramen magnum	Spinal cord; accessory nerve; vertebral arteries
Hypoglossal canal	Hypoglossal nerve to muscles of tongue
Sphenoid Bone	
Foramen ovale	Mandibular division of trigeminal nerve; accessory meningeal artery
Foramen rotundum	Maxillary division of trigeminal nerve
Optic canal	Optic nerve; ophthalmic artery
Superior orbital fissure	Oculomotor, trochlear, and abducens nerves; ophthalmic division of trigeminal nerve; ophthalmic veins
Maxilla	
Inferior orbital fissure	Infraorbital nerve; zygomatic nerve; infraorbital vessels
Infraorbital foramen	Infraorbital nerve and vessels
Mandible	
Mental foramen	Mental nerve and vessels
Mandibular foramen	Inferior alveolar nerves and vessels to the lower teeth

8.2a Cranial Bones

Bones of the skull are divided into two groups—*cranial bones*, which enclose the brain, and *facial bones*, which form the lower anterior part of the skull, including the jaws, nose, and parts of the orbit (**fig. 8.9**).

Cranial bones collectively compose the **cranium**³ (brain-case). The delicate brain tissue doesn't come directly into contact with the bones, but is separated from them by three membranes called the *meninges* (meh-NIN-jeez). The thickest and toughest of these, the *dura mater*⁴ (DUE-rah MAH-tur), is pressed against the inside of the cranium in most places and firmly attached to it at a few points.

The cranium is a rigid structure with an opening, the *foramen magnum* (literally “large hole”), where the spinal cord meets the brain. The cranium consists of two major parts—the calvaria and the base. The calvaria (skullcap) isn't a single bone but simply the dome of the top of the skull; it is composed of parts of multiple bones that form the roof and walls (see **fig. 8.8**). In skulls prepared

for study, the calvaria is often sawed so that part of it can be lifted off for examination of the interior. This reveals the **base** (floor) of the cranial cavity (see **fig. 8.5b**), which exhibits three paired depressions called cranial fossae. These correspond to the contour of the inferior surface of the brain (**fig. 8.10**). The relatively shallow **anterior cranial fossa** is crescent-shaped and accommodates the frontal lobes of the brain. The **middle cranial fossa**, which drops abruptly deeper, is shaped like a pair of outstretched bird's wings and accommodates the temporal lobes. The **posterior cranial fossa** is deepest and houses the brainstem and a large posterior division of the brain called the cerebellum.

There are eight cranial bones:

- | | |
|------------------|------------------|
| 1 frontal bone | 1 occipital bone |
| 2 parietal bones | 1 sphenoid bone |
| 2 temporal bones | 1 ethmoid bone |

The Frontal Bone

The **frontal bone** extends from the forehead back to a prominent *coronal suture*, which crosses the crown of the head from right to left and joins the frontal bone to the parietal bones (see **figs. 8.3** and **8.4**). The frontal bone forms the anterior wall and about one-third of the roof of the cranial cavity, and it turns inward to form nearly all of the anterior cranial fossa and the roof of the orbit.

³crani = helmet

⁴dura = tough, strong; mater = mother

FIGURE 8.9. Cranial and Facial Bones.

Deep to the eyebrows it has a ridge called the **supraorbital margin**. Each margin is perforated by a single **supraorbital foramen** (see figs. 8.3 and 8.15), which provides passage for a nerve, artery, and veins. In some people, the edge of this foramen breaks through the margin of the orbit and forms a *supraorbital notch*. A person may have a foramen on one supraorbital margin and a notch on the other. The smooth area of the frontal bone just above the root of the nose is called the **glabella**.⁵ The frontal bone also contains the frontal sinus. You may not see this sinus on all skulls. On some, the calvaria is cut too high to show it, and some people simply don't have one. Along the cut edge of the calvaria, you can also see the diploe (DIP-lo-ee)—the layer of spongy bone in the middle of the cranial bones (see fig. 8.5b).

The Parietal Bones

The right and left **parietal bones** (pa-RY-eh-tul) form most of the cranial roof and part of its walls (see figs. 8.4 and 8.8). Each is bordered by four sutures that join it to the neighboring bones: (1) a **sagittal suture** between the parietal bones; (2) the **coronal**⁶ suture at the anterior margin; (3) the **lambdoid**⁷ suture (LAM-doyd) at the posterior margin; and (4) the **squamous suture** laterally. Small sutural bones are often seen along the sagittal and lambdoid sutures, like little islands of bone with the suture lines passing around them. Internally, the parietal and frontal bones have markings that look a bit like aerial photographs of river tributaries (see fig. 8.4b). These represent places where the bone molded itself around blood vessels of the meninges.

⁵*glab* = smooth

⁶*corona* = crown

⁷Shaped like the Greek letter lambda (λ)

FIGURE 8.10 Cranial Fossae. (a) Superior view. (b) Lateral view showing how the three fossae conform to the contours of the base of the brain.

FIGURE 8.11 The Right Temporal Bone. (a) The lateral surface, facing the scalp and external ear. (b) The medial surface, facing the brain. **APR**

? List five bones that articulate with the temporal bone.

Externally, the parietal bones have few features. A **parietal foramen** sometimes occurs near the corner of the lambdoid and sagittal sutures (see fig. 8.8). It is an exit for a small vein from a blood sinus atop the brain. A pair of slight lateral thickenings, the superior and inferior **temporal lines**, form an arc across the parietal and frontal bones (see fig. 8.4a). They mark the attachment of the large, fan-shaped *temporalis muscle*, a chewing muscle that converges on the mandible.

The Temporal Bones

If you palpate your skull just above and anterior to the ear—that is, the temporal region—you can feel the **temporal bone**, which forms the lower wall and part of the floor of the cranial cavity (**fig. 8.11**). The temporal bone derives its name from the fact that people often develop their first gray hairs on the temples with the passage of time.⁸ The relatively complex shape of the temporal bone is best understood by dividing it into four parts:

1. The **squamous**⁹ part (which you just palpated) is relatively flat and vertical. It is encircled by the squamous suture. It bears

two prominent features: (a) the **zygomatic process**, which extends anteriorly to form part of the *zygomatic arch*, described later; and (b) the **mandibular fossa**, a depression where the mandible articulates with the cranium.

2. The **tympanic**¹⁰ part is a small ring of bone that borders the opening of the **external acoustic meatus** (me-AY-tus), or ear canal. It has a pointed spine on its inferior surface, the **styloid process**, named for its resemblance to the stylus used by ancient Greeks and Romans to write on wax tablets. The styloid process provides attachment for muscles of the tongue, pharynx, and hyoid bone.
3. The **mastoid**¹¹ part lies posterior to the tympanic part. It bears a heavy **mastoid process**, which you can palpate as a prominent lump behind the earlobe. It is filled with small air sinuses that communicate with the middle-ear cavity. These sinuses are subject to infection and inflammation (*mastoiditis*), which can erode the bone and spread to the brain. A groove called the **mastoid notch** lies medial to the mastoid process (see fig. 8.5a). It is the superior attachment of the *digastric muscle*, which opens the mouth. The notch is perforated at its anterior end by the **stylomastoid foramen**, which is a passage for a branch of the facial nerve, and at its posterior end by the **mastoid foramen**, which passes a small artery and vein from the brain.
4. The **petrous**¹² part can be seen in the cranial floor, where it resembles a little mountain range separating the middle cranial fossa from the posterior fossa (fig. 8.11b). It houses the middle- and inner-ear cavities. The **internal acoustic meatus**, an opening on its posteromedial surface, allows passage of a nerve that carries signals for hearing and balance from the inner ear to the brain. On the inferior surface of the petrous part are two prominent foramina named for the major blood vessels that pass through them (see fig. 8.5a): (a) The **carotid canal** is a passage for the internal carotid artery, a major blood supply to the brain. This artery is so close to the inner ear that one can sometimes hear the pulsing of its blood when the ear is resting on a pillow or the heart is beating hard. (b) The **jugular foramen** is a large, irregular opening just medial to the styloid process, between the temporal and occipital bones. Blood from the brain drains through this foramen into the internal jugular vein of the neck. Three cranial nerves also pass through this foramen (see table 8.3).

The Occipital Bone

The **occipital bone** (oc-SIP-ih-tul) forms the rear of the skull (*occiput*) and much of its base (see fig. 8.5). Its most conspicuous feature, the **foramen magnum**, admits the spinal cord to the cranial cavity; the dura mater is attached to the rim of this foramen. An important consideration in head injuries is swelling of the brain.

⁸tempor = time

⁹squam = flat; ous = characterized by

¹⁰tympan = drum (eardrum); ic = pertaining to

¹¹mast = breast; oid = shaped like

¹²petr = stone, rock; ous = like

Since the cranium cannot expand, swelling puts pressure on the brain and results in even more tissue damage. Severe swelling can force the brainstem out through the foramen magnum, usually with fatal consequences.

The occipital bone continues anterior to this as a thick median plate, the **basilar part**. On either side of the foramen magnum is a smooth knob called the **occipital condyle** (CON-dile), where the skull rests on the vertebral column. Passing like a tunnel beneath each condyle is a **hypoglossal**¹³ **canal**, named for the *hypoglossal nerve* that passes through it to innervate the muscles of the tongue. In some people, a **condylar canal** (CON-dih-lur) is found posterior to each occipital condyle. A small vein from a blood sinus of the brain passes through here.

Internally, the occipital bone displays impressions left by large venous sinuses that drain blood from the brain (see fig. 8.5b). One of these grooves travels along the median line. Just before reaching the foramen magnum, it branches into right and left grooves that wrap around the occipital bone like outstretched arms before terminating at the jugular foramina. The venous sinuses that occupy these grooves are described in chapter 20.

Other features of the occipital bone can be palpated on the back of your head. One is a prominent medial bump called the **external occipital protuberance**—the attachment for the **nuchal**¹⁴ **ligament** (NEW-kul), which binds the skull to the vertebral column. A ridge, the **superior nuchal line**, can be traced horizontally

from this protuberance toward the mastoid process (see fig. 8.5a). It defines the superior limit of the neck and provides attachment to the skull for several neck and back muscles. It forms the boundary where, in palpating the upper neck, you feel the transition from muscle to bone. By pulling down on the occipital bone, some of these muscles help to keep the head erect. The deeper **inferior nuchal line** provides attachment for some of the deep neck muscles. This inconspicuous ridge can't be palpated on the living body but is visible on an isolated skull.

The Sphenoid Bone

The **sphenoid**¹⁵ **bone** (SFEE-noyd) has a complex shape with a thick median **body** and outstretched **greater** and **lesser wings**, which give the bone as a whole a ragged mothlike shape. Most of it is best seen from the superior perspective (**fig. 8.12a**). In this view, the lesser wings form the posterior margin of the anterior cranial fossa and end at a sharp bony crest, where the sphenoid drops abruptly to the greater wings. The greater wings form about half of the middle cranial fossa (the temporal bone forming the rest) and are perforated by several foramina.

The greater wing also forms part of the lateral surface of the cranium just anterior to the temporal bone (see fig. 8.4a). The lesser wing forms the posterior wall of the orbit and contains the **optic canal**, which permits passage of the optic nerve and ophthalmic

¹³*hypo* = below; *gloss* = tongue

¹⁴*nucha* = back of the neck

¹⁵*sphen* = wedge; *oid* = resembling

FIGURE 8.12 The Sphenoid Bone. (a) Superior view. (b) Posterior view, as if looking from the back of the head into the opened skull.

artery (see fig. 8.15). Superiorly, a pair of bony spines of the lesser wing called the **anterior clinoid processes** appears to guard the optic foramina. The **superior orbital fissure**, a slit in the posterior wall of the orbit, angles upward lateral to the optic canal. It serves as a passage for three nerves that supply the muscles of eye movement.

The body of the sphenoid bone (fig. 8.12b) contains a pair of sphenoidal sinuses and has a saddlelike surface feature named the **sella turcica**¹⁶ (SEL-la TUR-sih-ca). The sella consists of a deep pit called the *hypophyseal fossa*, which houses the pituitary gland (hypophysis); a raised anterior margin called the *tuberculum sellae* (too-BUR-cu-lum SEL-lee); and a posterior margin called the *dorsum sellae*. In life, the dura mater stretches over the sella turcica and attaches to the anterior clinoid processes. A stalk penetrates the dura to connect the pituitary gland to the base of the brain.

Lateral to the sella turcica, the greater wings are perforated by several foramina (see fig. 8.5a). The **foramen rotundum** and **foramen ovale** (oh-VAY-lee) are passages for two branches of the trigeminal nerve. The **foramen spinosum**, about the diameter of a pencil lead, provides passage for an artery of the meninges. An irregular gash called the **foramen lacerum**¹⁷ (LASS-eh-rum) occurs at the junction of the sphenoid, temporal, and occipital bones. It is filled with cartilage in life and transmits no major vessels or nerves.

In an inferior view of the skull, the sphenoid can be seen just anterior to the basilar part of the occipital bone. The internal openings of the nasal cavity seen here are called the **posterior nasal apertures**, or **choanae**¹⁸ (co-AH-nee). Lateral to each aperture, the sphenoid bone exhibits a pair of parallel plates—the **medial**

and **lateral pterygoid**¹⁹ plates (TERR-ih-goyd) (see fig. 8.5a). Each plate has a narrower inferior extension called the **pterygoid process**. These plates and processes provide attachment for some of the jaw muscles described in chapter 10.

The Ethmoid Bone

The **ethmoid**²⁰ bone (ETH-moyd) is an anterior cranial bone located between the eyes (figs. 8.6 and 8.13). It contributes to the medial wall of the orbit, the roof and walls of the nasal cavity, and the nasal septum. It is a very porous and delicate bone, with three major portions:

1. The vertical **perpendicular plate**, a thin median plate of bone that forms the superior two-thirds of the nasal septum (see fig. 8.4b). (The lower part is formed by the *vomer*, discussed later.) The septum divides the nasal cavity into right and left air spaces called the **nasal fossae** (FOSS-ee). The septum is often curved, or deviated, toward one nasal fossa or the other.
2. A horizontal **cribriform**²¹ plate (CRIB-rih-form), which forms the roof of the nasal cavity. This plate has a median blade called the **crista galli**²² (GAL-eye), an attachment point for the dura mater. On each side of the crista is an elongated depressed area perforated with numerous holes, the **cribriform (olfactory) foramina**. A pair of *olfactory bulbs* of the brain, concerned with the sense of smell, rests in these depressions, and the foramina allow passage for olfactory nerves from the nasal cavity to the bulbs.
3. The **ethmoidal labyrinths** are large masses on each side of the perpendicular plate. They are named for the fact that internally they have a maze of air spaces called the **ethmoidal cells**. Collectively, these constitute the *ethmoidal sinus* discussed earlier. The lateral surface of each labyrinth is a smooth, slightly concave **orbital plate** seen on the medial wall of the orbit (see fig. 8.15). The medial surface of each labyrinth gives rise to two curled, scroll-like plates of bone called the **superior and middle nasal conchae**²³ (CON-kee). These project into the nasal fossa from the lateral walls toward the septum (see figs. 8.6 and 8.14). There is also a separate bone in each fossa, the *inferior nasal concha*, discussed later. The conchae occupy most of the nasal cavity, leaving little open space. By filling space and creating turbulence in the flow of inhaled air, they ensure that the air contacts the mucous membranes that cover these bones, which cleanse, humidify, and warm the inhaled air before it reaches the lungs. The superior concha and adjacent part of the nasal septum also bear the sensory cells of smell.

The deep position of the ethmoid bone makes most of it difficult to see on an intact skull. The perpendicular plate and middle nasal concha can be seen by looking into the nasal cavity

¹⁶sella = saddle; turcica = Turkish

¹⁷lacerum = torn, lacerated

¹⁸choana = funnel

FIGURE 8.13 The Ethmoid Bone (Anterior View). APR

(see fig. 8.3); the orbital plate by looking at the medial wall of the orbit (**fig. 8.15**); and the crista galli and cribriform plate from within the cranial cavity (see fig. 8.5b).

8.2b Facial Bones

Facial bones do not enclose the brain but lie anterior to the cranial cavity (see fig. 8.9). They support the orbital, nasal, and oral

cavities, shape the face, and provide attachment for the muscles of facial expression and mastication. There are 14 facial bones:

2 maxillae	2 nasal bones
2 palatine bones	2 inferior nasal conchae
2 zygomatic bones	1 vomer
2 lacrimal bones	1 mandible

The Maxillae

The **maxillae** (mac-SILL-ee) are the largest facial bones. They form the upper jaw and meet each other at a median *intermaxillary suture* on the midline of the palate (see figs. 8.3, 8.4a, and 8.5a). Small points of maxillary bone called **alveolar processes** grow into the spaces between the bases of the teeth. The root of each tooth is inserted into a deep socket, or **alveolus**. If a tooth is lost or extracted so that chewing no longer puts stress on the maxilla, the alveolar processes are resorbed and the alveolus fills in with new bone, leaving a smooth area on the maxilla.

Although they are preserved with the skull, the teeth are not bones. They are discussed in detail in chapter 25.

▶▶▶ APPLY WHAT YOU KNOW

Suppose you were studying a skull with some teeth missing. How could you tell whether the teeth had been lost after the person's death or years before it?

Each maxilla extends from the teeth to the inferomedial wall of the orbit. Just below the orbit, it exhibits an **infraorbital foramen**, which provides passage for blood vessels to the face and a nerve that receives sensations from the nasal region and cheek. This nerve emerges through the foramen rotundum into the cranial cavity. The maxilla forms part of the floor of the orbit, where it meets the sphenoid and zygomatic bones to form a slit called the **inferior orbital fissure**, which angles downward and laterally (fig. 8.15). The inferior and superior orbital fissures form a sideways V whose apex lies near the optic canal. The inferior orbital fissure is a passage for blood vessels and sensory nerves from the face.

The **palate** forms the roof of the mouth and floor of the nasal cavity. Its function is to separate the nasal cavity from the oral cavity, enabling us (and other mammals) to continue breathing while chewing. The high metabolic rate of humans requires rapid digestion of food, which in turn is aided by prolonged and thorough mastication into small, easily digested particles. This would be difficult if such prolonged mastication required an interruption of airflow.

The palate consists of a bony **hard palate** anteriorly and a fleshy **soft palate** posteriorly. Most of the hard palate is formed by horizontal extensions of the maxilla called **palatine processes** (PAL-uh-tine) (see fig. 8.5a). Just behind the incisors (front teeth) is a median pit, the **incisive fossa**, which is a passage for an artery to the palate and a nerve to the lower part of the nasal septum and the six front teeth of the maxilla. One or two pairs of *incisive foramina* open deep within this fossa (fig. 8.14) but are difficult to see. The palatine processes normally meet at the intermaxillary suture at about 12 weeks of gestation. Failure to join results in a *cleft palate* (see Deeper Insight 29.4).

The Palatine Bones

The **palatine bones** each have an L shape formed by a *horizontal plate* and a *perpendicular plate* (fig. 8.14). The horizontal plates form the posterior one-third of the hard palate, further separating

the oral and nasal cavities (see fig. 8.5a). Each is marked by a large **greater palatine foramen**, a nerve passage to the palate. The perpendicular plate is a thin, delicate, irregularly shaped plate that forms part of the wall between the nasal cavity and the orbit.

The Zygomatic Bones

The **zygomatic**²⁴ bones, colloquially called the cheekbones, form the angles of the cheeks at the inferolateral margins of the orbits and part of the lateral wall of each orbit; they extend about halfway to the ear (see figs. 8.4a, 8.5a, and 8.15). Each zygomatic bone has an inverted T shape and usually a small **zygomaticofacial foramen** (ZY-go-MAT-ih-co-FAY-shul) near the intersection of the stem and crossbar of the T. A nerve passes through here to supply the skin on the prominence of the cheek. The prominent **zygomatic arch** that flares from each side of the skull is formed mainly by parts of the zygomatic bone, temporal bone, and maxilla (see fig. 8.4a).

The Lacrimal Bones

The **lacrimal**²⁵ bones (LACK-rih-mul) form part of the medial wall of each orbit (fig. 8.15). They are the smallest bones of the skull, about the size of the little fingernail. A depression in this bone houses a membranous *lacrimal sac* in life. Tears from the eye collect in this sac and drain into the nasal cavity.

The Nasal Bones

Two small rectangular **nasal bones** form the bridge of the nose (see fig. 8.3) and support cartilages that shape its lower portion. If you palpate the bridge, you can easily feel where the nasal bones end and the cartilages begin. The nasal bones are often fractured by blows to the nose.

The Inferior Nasal Conchae

There are three conchae in each nasal fossa. The superior and middle conchae, as discussed earlier, are parts of the ethmoid bone. The **inferior nasal concha**—the largest of the three—is a separate bone (fig. 8.14).

The Vomer

The **vomer** forms the inferior one-third of the bony nasal septum (see figs. 8.3 and 8.4b). Its name literally means “plowshare,” which refers to its resemblance to the blade of a plow. The superior two-thirds of the septum is formed by the perpendicular plate of the ethmoid bone, as mentioned earlier. The vomer and perpendicular plate support a wall of *septal cartilage* that forms most of the anterior part of the septum.

²⁴zygo = to join, unite

²⁵lacrim = tear, to cry

FIGURE 8.16 The Mandible. **APR**

The Mandible

The **mandible** (fig. 8.16) is the strongest bone of the skull and the only one that can move significantly. It supports the lower teeth and provides attachment for muscles of mastication and facial expression. The horizontal portion, bearing the teeth, is called the **body**; the vertical to oblique posterior portion is the **ramus** (RAY-mus) (plural, *rami*); and these two portions meet at a corner called the **angle**. The mandible develops as separate right and left bones in the fetus, joined by a median cartilaginous joint called the **mental symphysis** (SIM-fih-sis) at the point of the chin. This joint ossifies in early childhood, uniting the two halves into a single bone. The point of the chin itself is called the **mental protuberance**. The inner (posterior) surface of the mandible in this region has a pair of small points, the **mental spines**, which serve for attachment of certain chin muscles (see fig. 8.4b).

On the anterolateral surface of the body, the **mental foramen** permits the passage of nerves and blood vessels of the chin. The inner surface of the body has a number of shallow depressions and ridges to accommodate muscles and salivary glands. The angle of the mandible has a rough lateral surface for insertion of the *masseter*, a muscle of mastication. Like the maxilla, the mandible has pointed alveolar processes between the teeth.

The ramus is somewhat Y-shaped. Its posterior branch, called the **condylar process** (CON-dih-lur), bears the **mandibular condyle**—an oval knob that articulates with the mandibular fossa of the temporal bone. The meeting of this condyle with the temporal bone forms a hinge, the **temporomandibular joint (TMJ)**. The anterior branch of the ramus is a blade called the **coronoid process**. It is the point of insertion for the temporalis muscle, which pulls the mandible upward when you bite. The U-shaped arch between the two processes is the **mandibular notch**. Below the notch, on the medial surface of the ramus, is the **mandibular foramen**. The nerve and blood vessels that supply the lower teeth enter this foramen and then travel through the bone of the mandibular body, giving off branches to each tooth along the way. Dentists commonly inject lidocaine near the mandibular foramen to deaden sensation from the lower teeth.

8.2c Bones Associated with the Skull

Seven bones are closely associated with the skull but not considered to be part of it. These are the three auditory ossicles in each middle-ear cavity and the hyoid bone beneath the chin. The **auditory ossicles**²⁶—named the **malleus** (hammer), **incus** (anvil), and **stapes** (STAY-pee-z) (stirrup)—are discussed in connection with hearing in chapter 16.

The **hyoid**²⁷ bone is a slender U-shaped bone between the chin and larynx (fig. 8.17). It is one of the few bones that doesn't articulate with any other. It is suspended from the styloid processes of the skull, somewhat like a hammock, by the small *stylohyoid muscles* and *stylohyoid ligaments*. The median **body** of the hyoid is flanked on either side by hornlike projections called the **greater** and **lesser horns** (**cornua**). The larynx (voice box) is suspended from the hyoid bone by a broad ligament, and the hyoid serves for attachment of several muscles that control the mandible, tongue, and larynx. Forensic pathologists look for a fractured hyoid as evidence of strangulation.

8.2d The Skull in Infancy and Childhood

The head of an infant couldn't fit through the mother's pelvic outlet at birth if not for the fact that the bones of its skull are not yet fused. The shifting of the cranial bones during birth may cause the infant's head to appear deformed, but it soon assumes a more normal shape. Spaces between the unfused cranial bones are called **fontanelles**,²⁸ after the fact that pulsation of the infant's blood can be felt there. The bones are joined at these points only by fibrous membranes, in which intramembranous ossification is completed later (see fig. 7.10). Four of these sites are especially prominent and regular in location: the **anterior**, **posterior**, **sphenoid** (anterolateral), and

²⁶*os* = bone; *icle* = little

²⁷*hy* = the letter U; *oid* = resembling

²⁸*fontan* = fountain; *elle* = little

FIGURE 8.17 The Hyoid Bone.

DEEPER INSIGHT 8.1

CLINICAL APPLICATION

Cranial Assessment of the Newborn

Obstetric nurses routinely assess the fontanelles of newborns by palpation. In a difficult delivery, one cranial bone may override another along a suture line, which calls for close monitoring of the infant. Abnormally wide sutures may indicate hydrocephalus, the accumulation of excessive amounts of cerebrospinal fluid, which causes the cranium to swell. Bulging fontanelles suggest abnormally high intracranial pressure, while depressed fontanelles indicate dehydration.

mastoid (posterolateral) fontanelles (fig. 8.18). Most fontanelles ossify by the time the infant is a year old, but the largest one—the anterior fontanelle—can still be palpated 18 to 24 months after birth.

The frontal bone and mandible are separate right and left bones at birth, but fuse medially in early childhood. The frontal bones usually fuse by age 5 or 6, but they remain separated by a

persistent metopic²⁹ suture in many people, with differences between ethnic groups. There is a very high frequency in India and Nigeria, for example, and they are twice as common in American females as in males.

The face of a newborn is flat and the cranium relatively large. To accommodate the growing brain, the skull grows more rapidly than the rest of the skeleton during childhood. It reaches about half its adult size by 9 months of age, three-quarters by age 2, and nearly final size by 8 or 9 years. The heads of babies and children are therefore much larger in proportion to the trunk than the heads of adults—an attribute thoroughly exploited by cartoonists and advertisers who draw big-headed characters to give them a more endearing or immature appearance. In humans and other animals, the large, rounded heads of the young are thought to promote survival by stimulating parental caregiving instincts.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

4. Name the paranasal sinuses and state their locations. Name any four other cavities in the skull.
5. Explain the difference between a cranial bone and a facial bone. Give four examples of each.
6. Draw an oval representing a superior view of the calvaria. Draw lines representing the coronal, lambdoid, and sagittal sutures. Label the four bones separated by these sutures.
7. State which bone has each of these features: a squamous part, hypoglossal canal, greater horn, greater wing, condylar process, and cribriform plate.
8. Determine which of the following structures can't normally be palpated on a living person: the mastoid process, crista galli, superior orbital fissure, palatine processes, zygomatic bone, mental protuberance, and stapes. You may find it useful to palpate some of these on your own skull as you try to answer.

FIGURE 8.18 The Fetal Skull Near the Time of Birth. (a) Lateral view. (b) Superior view of the calvaria.

8.3 The Vertebral Column and Thoracic Cage

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the general features of the vertebral column and those of a typical vertebra;
- b. describe the structure of the intervertebral discs and their relationship to the vertebrae;
- c. describe the special features of vertebrae in different regions of the vertebral column, and discuss the functional significance of the regional differences; and
- d. describe the anatomy of the sternum and ribs and how the ribs articulate with the thoracic vertebrae.

²⁹met = beyond; op = the eyes

8.3a General Features of the Vertebral Column

The **vertebral column (spine)** physically supports the skull and trunk, allows for their movement, protects the spinal cord, and absorbs stresses produced by walking, running, and lifting. It also provides attachment for the limb girdles, thoracic cage, and postural muscles. Although commonly called the backbone, it consists of not a single bone but a flexible chain of usually 33 **vertebrae** with **intervertebral discs** of fibrocartilage between most of them.

The adult vertebral column averages about 71 cm (28 in.) long, with the intervertebral discs accounting for about one-quarter of the length. Most people are about 1% shorter when they go to bed at night than when they first rise in the morning. This is because during the day, the weight of the body compresses the intervertebral discs and squeezes water out of them. When one is sleeping, with the weight off the spine, the discs reabsorb water and swell.

As shown in **figure 8.19**, the vertebrae are divided into five groups, usually numbering 7 *cervical vertebrae* (SUR-vih-cul)

in the neck, 12 *thoracic vertebrae* in the chest, 5 *lumbar vertebrae* in the lower back, 5 *sacral vertebrae* at the base of the spine, and up to 5 (usually 4) tiny *coccygeal vertebrae* (coc-SIDJ-ee-ul). To help remember the numbers of cervical, thoracic, and lumbar vertebrae—7, 12, and 5—think of a typical workday: Go to work at 7, have lunch at 12, and go home at 5. All mammals have 7 cervical vertebrae, even in the famously long necks of giraffes.

Variations in this arrangement occur in about 1 person in 20. For example, the last lumbar vertebra is sometimes incorporated into the sacrum, producing four lumbar and six sacral vertebrae. In other cases, the first sacral vertebra fails to fuse with the second, producing six lumbar and four sacral vertebrae. The cervical and thoracic vertebrae are more constant in number.

Beyond the age of 3 years, the vertebral column has four bends that give it an undulating S shape (**fig. 8.20**). A bend that is concave in the anterior direction (curved outward toward the back) is called a **kyphosis**.³⁰ There are two of these, the *thoracic kyphosis* and *sacral kyphosis*. A bend toward the front, concave

FIGURE 8.20 Adult Spinal Curvatures.

FIGURE 8.21 Spinal Curvature of the Newborn Infant. At this age, the spine forms a single C-shaped curve.

Bob Coyle/McGraw Hill

posteriorly, is called a **lordosis**,³¹ and there are also two of these—the *cervical lordosis* and *lumbar lordosis*. These aren't present in the newborn, whose spine exhibits one continuous C-shaped curve, as it does in monkeys, apes, and most other four-legged animals (**fig. 8.21**). As an infant begins to crawl and lift its head, the cervical region becomes curved toward the posterior side, enabling an infant on its belly to look up. As a toddler begins walking, another curve develops in the same direction in the lumbar region. The resulting S shape makes sustained bipedal walking possible (see Deeper Insight 8.4). The thoracic and sacral kyphoses are called *primary curvatures* because they exist from birth. The cervical and lumbar lordoses are called *secondary curvatures* because they develop later, in the child's first few years of crawling and walking. Abnormal lateral and anteroposterior curvatures are among the most common disorders of the spine (see Deeper Insight 8.2).

8.3b General Structure of a Vertebra

A representative vertebra and intervertebral disc are shown in **figure 8.23**. The largest feature of a vertebra is the **body (centrum)**—a mass of spongy bone and red bone marrow covered with a thin shell of compact, cortical bone. This is the weight-bearing portion of the vertebra. Its rough superior and inferior surfaces provide firm attachment to the intervertebral discs.

³¹lordo = backward; osis = condition

DEEPER INSIGHT 8.2

CLINICAL APPLICATION

Abnormal Spinal Curvatures

Abnormal spinal curvatures (**fig. 8.22**) can result from disease, weakness or paralysis of the trunk muscles, poor posture, pregnancy, or congenital defects in vertebral anatomy. The most common deformity is an abnormal lateral curvature called **scoliosis**. It occurs most often in the thoracic region, particularly among adolescent girls. It sometimes results from a developmental abnormality in which the body and arch fail to develop on one side of a vertebra. If the person's skeletal growth is not yet complete, scoliosis can be corrected with a back brace.

An exaggerated thoracic curvature is called **hyperkyphosis**. It is usually a result of osteoporosis (see **fig. 7.21**), but also occurs in people with osteomalacia or spinal tuberculosis and in adolescents who engage heavily in such spine-loading sports as wrestling and weight lifting. An exaggerated lumbar curvature is called **hyperlordosis**. It may have the same causes as hyperkyphosis, or it may result from added abdominal weight in pregnancy or obesity.

▶▶▶ APPLY WHAT YOU KNOW

The vertebral bodies and intervertebral discs get progressively larger as we look lower and lower on the vertebral column. What is the functional significance of this trend?

Arising from the posterior side of the body is a bony **vertebral arch**. This consists of two parts on each side: a pillarlike **pedicle**³² and platelike **lamina**.³³ Extending from the apex of the arch, a projection called the **spinous process** is directed posteriorly and downward. You can see and feel the spinous processes on a living person as a row of bumps along the spine. A **transverse process** extends laterally from the point where the pedicle and lamina meet. The spinous and transverse processes provide points of attachment for ligaments, ribs, and spinal muscles.

A pair of **superior articular processes** projects upward from one vertebra and meets a similar pair of inferior articular processes that projects downward from the vertebra above (**fig. 8.25a**). Each process has a flat articular surface (facet) facing that of the adjacent vertebra. These processes restrict twisting of the vertebral column, which could otherwise severely damage the spinal cord.

The body and vertebral arch enclose a triangular space called the **vertebral foramen**. The 29 vertebral foramina collectively form the **vertebral canal**, a passage for the spinal cord.

Where two vertebrae meet, they exhibit an opening on each side between their pedicles called the **intervertebral foramen**. These foramina allow passage for spinal nerves that connect with the spinal cord at regular intervals. Each foramen is formed by an **inferior vertebral notch** in the pedicle of the upper vertebra and a **superior vertebral notch** in the pedicle of the lower one (**fig. 8.25b**).

8.3c Intervertebral Discs

An intervertebral disc is a cartilaginous pad located between the bodies of two adjacent vertebrae. It consists of an inner gelatinous **nucleus pulposus** surrounded by a ring of fibrocartilage, the **annulus fibrosus** (see **fig. 8.23b**). There are 23 discs—the first one between cervical vertebrae 2 and 3 (C2–C3) and the last one between the last lumbar vertebra and the sacrum (L5–S1). They help to bind adjacent vertebrae together, support the weight of the body, allow spinal mobility, and absorb shock. Discs can rupture painfully when subjected to excessive stress (see Deeper Insight 8.3).

DEEPER INSIGHT 8.3 CLINICAL APPLICATION

Herniated Disc

Stress on the vertebral column, as in lifting a heavy weight, compresses the intervertebral discs and makes them bulge laterally. Excessive stress can crack the annulus fibrosus, allowing the gelatinous nucleus pulposus to ooze out (**fig. 8.24**). This is called a **herniated disc** (colloquially, a “ruptured disc,” or more inaccurately, “slipped disc”). Herniation usually occurs at the posterolateral corners of the discs because the annulus fibrosus is thinnest on the posterior side and the corners are least supported by nearby spinal ligaments. About 95% of herniations are at the L4–L5 or L5–S1 level because these bear the most weight. Disc herniation rarely occurs in young people because of their well-hydrated, thick, resilient discs. Herniated discs are one of the most common causes of lower back pain, stemming from inflammation stimulated by the nucleus and pressure of the oozing nucleus on spinal nerve roots passing through this tight space. Over 80% of patients recover from the pain with only oral analgesics, requiring no surgery; up to 76% of cases resolve partially or completely within 1 year.

FIGURE 8.24 Herniated Disc.

³²ped = foot; icle = little

³³lamina = plate

FIGURE 8.25 Articulated Vertebrae. (a) Posterior view. (b) Left lateral view.

8.3d Regional Characteristics of Vertebrae

We are now prepared to consider how vertebrae differ from one region of the vertebral column to another and from the generalized anatomy just described. Knowing these variations will enable you to identify the region of the spine from which an isolated vertebra was taken. More importantly, these modifications in form reflect functional differences among the vertebrae.

The Cervical Vertebrae

The cervical vertebrae (C1–C7) are relatively small. Their function is to support the head and allow for its movements. The first two (C1 and C2) have unique structures for this purpose (**fig. 8.26**). Vertebra C1 is called the **atlas** because it supports the head in a manner reminiscent of Atlas, the giant of Greek mythology who was condemned by Zeus to carry the heavens

FIGURE 8.26 The Atlas and Axis, Cervical Vertebrae C1 and C2. (a) The atlas, superior view. (b) The axis, posterosuperior view. (c) Articulation of the atlas and axis and rotation of the atlas. This movement turns the head from side to side, as in gesturing “no.” Note the transverse ligament holding the dens of the axis in place. **APR**

? What serious consequence could result from a rupture of the transverse ligament?

on his shoulders. It scarcely resembles the typical vertebra; it has no body, and is little more than a delicate ring surrounding a large vertebral foramen. On each side is a **lateral mass** with a deeply concave **superior articular facet** that articulates with the occipital condyle of the skull. A nodding motion of the skull, as in gesturing “yes,” causes the occipital condyles to rock back and forth on these facets. The **inferior articular facets**, which are comparatively flat or only slightly concave, articulate with C2. The lateral masses are connected by an **anterior arch** and a **posterior arch**, which bear slight protuberances called the **anterior** and **posterior tubercle**, respectively.

Vertebra C2, the **axis**, allows rotation of the head as in gesturing “no.” Its most distinctive feature is a prominent knob called the **dens** (pronounced “denz”), or **odontoid**³⁴ **process**, on its anterosuperior side. No other vertebra has a dens. It serves as

the axis of rotation for the head and gives it a much greater range of motion than it would have if the first two vertebrae articulated like those below C2. The dens begins to form as an independent ossification center during the first year after birth and fuses with the axis by the age of 3 to 6 years. It projects into the vertebral foramen of the atlas, where it is nestled in a facet and held in place by a **transverse ligament** (fig. 8.26c). A heavy blow to the top of the head can cause a fatal injury in which the dens is driven through the foramen magnum into the brainstem.

The articulation between the atlas and the cranium is called the **atlanto–occipital joint**; the one between the atlas and axis is called the **atlantoaxial joint**.

The axis is the first vertebra to exhibit a spinous process. In vertebrae C2 through C6, the process is forked, or *bifid*,³⁵ at its tip (fig. 8.27a). This fork provides attachment for the *nuchal*

³⁴*dens* = *odont* = tooth; *oid* = resembling

³⁵*bifid* = branched, cleft into two parts

FIGURE 8.27 Regional Differences in Vertebrae. (a) Cervical vertebrae. (b) Thoracic vertebrae. (c) Lumbar vertebrae. The left-hand figures are superior views and the right-hand figures are left lateral views. **APR**

ligament of the back of the neck. All seven cervical vertebrae have a prominent round **transverse foramen** in each transverse process. These foramina provide passage and protection for the *vertebral arteries*, which supply blood to the brain, and *vertebral veins*, which drain blood from various neck structures (but not from the brain). Transverse foramina occur in no other vertebrae and thus provide an easy means of recognizing a cervical vertebra.

Cervical vertebrae C3 through C6 are similar to the typical vertebra depicted in figure 8.23a, with the addition of the transverse foramina and bifid spinous processes. Vertebra C7 is a little different—its spinous process is not bifid, but is especially long and forms a prominent bump on the lower back of the neck. C7 is sometimes called the *vertebra prominens* because of this prominent spinous process. This feature is a convenient landmark for counting vertebrae by palpation. One can easily identify the largest bump on the neck as C7, then count up or down from there to identify others.

The Thoracic Vertebrae

There are 12 **thoracic vertebrae** (T1–T12), corresponding to the 12 pairs of ribs attached to them; no other vertebrae have ribs. One function of the thoracic vertebrae is to support the thoracic cage enclosing the heart and lungs. They lack the transverse foramina and bifid processes that distinguish the cervical vertebrae, but possess the following distinctive features of their own (fig. 8.27b):

- The spinous processes are relatively pointed and angle sharply downward.
- The body is somewhat heart-shaped, heavier than in the cervical vertebrae but less than in the lumbar vertebrae.
- The body has small, smooth, slightly concave spots called *costal facets* for attachment of the ribs.
- Vertebrae T1 through T10 have a shallow, cuplike **transverse costal**³⁶ **facet** at the end of each transverse process. These provide a second point of articulation for ribs 1 to 10. There are no transverse costal facets on T11 and T12 because ribs 11 and 12 attach only to the bodies of those two vertebrae.

Thoracic vertebrae vary among themselves mainly in the mode of articulation with the ribs (see fig. 8.31). In most cases, a rib inserts between two vertebrae, so each vertebra contributes one-half of the articular surface. A rib articulates with the **inferior costal facet** of the upper vertebra and the **superior costal facet** of the vertebra below that. This terminology may be a little confusing, but note that the superior and inferior facets are named for their position on the vertebral body, not for which part of the rib's articulation they provide. Vertebrae T1 and T10 through T12, however, have complete costal facets on the bodies for ribs 1 and 10 through 12, which articulate on the vertebral bodies instead of between vertebrae. Vertebrae T11 and T12, as noted, have no transverse costal facets. These variations will

be more functionally understandable after you have studied the anatomy of the ribs, so we will return then to the details of these articular surfaces.

Each thoracic vertebra has a pair of superior articular facets that face posteriorly and a pair of inferior articular facets that face anteriorly (except in vertebra T12). Thus, the superior facets that project upward from one vertebra articulate with the inferior facets that project downward from the next one above it. In vertebra T12, however, the inferior articular facets face somewhat laterally instead of anteriorly. This positions them to articulate with the medially facing superior articular facets of the first lumbar vertebra. T12 thus shows an anatomical transition between the thoracic and lumbar pattern, described next.

The Lumbar Vertebrae

There are five **lumbar vertebrae** (L1–L5). Their most distinctive features are a thick, stout body and a blunt, squarish spinous process for attachment of the strong lumbar muscles (fig. 8.27c). In addition, their articular processes are oriented differently than on other vertebrae. The superior processes face medially (like the palms of your hands about to clap), and the inferior processes face laterally, toward the superior processes of the next vertebra. This arrangement resists twisting of the lower spine. These differences are best observed on an articulated skeleton.

The Sacrum

The **sacrum** (SACK-rum, SAY-krum) is a bony plate that forms the posterior wall of the pelvic girdle (fig. 8.28). It was named *sacrum* for its prominence as the largest and most durable bone of the vertebral column.³⁷ There are five separate **sacral vertebrae** (S1–S5) in children, but they begin to fuse around age 16 and are fully fused by age 26.

The anterior surface of the sacrum is relatively smooth and concave and has four transverse lines that indicate where the five vertebrae have fused. This surface exhibits four pairs of large **anterior sacral foramina**, which allow for passage of nerves to the pelvic organs and lower limbs. The posterior surface is very rough. The spinous processes of the vertebrae fuse into a ridge called the **median sacral crest**. The transverse processes fuse into a less prominent **lateral sacral crest** on each side of the median crest. Again on the posterior side of the sacrum, there are four pairs of openings for spinal nerves, the **posterior sacral foramina**. The nerves that emerge here supply the gluteal region.

A **sacral canal** runs through the sacrum and ends in an inferior opening called the **sacral hiatus** (hy-AY-tus). This canal contains spinal nerve roots. On each side of the sacrum is an ear-shaped region called the **auricular**³⁸ **surface** (aw-RIC-you-lur). This articulates with a similarly shaped surface on the hip bone (see fig. 8.38b) and forms the strong, nearly immovable **sacroiliac**

³⁶*costa* = rib; *al* = pertaining to

³⁷*sacr* = great, prominent

³⁸*auri* = ear; *cul* = little; *ar* = pertaining to

FIGURE 8.28 The Sacrum and Coccyx. (a) The anterior surface, which faces the viscera of the pelvic cavity. (b) The posterior surface. The processes of this surface can be palpated in the sacral region. **APR**

(SI) joint (SACK-ro-ILL-ee-ac). The body of vertebra S1 juts anteriorly to form a **sacral promontory**, which supports the body of vertebra L5. Lateral to the median sacral crest, S1 also has a pair of **superior articular processes** that articulate with vertebra L5. Lateral to these is a pair of large, rough, winglike extensions called the **alae**³⁹ (AIL-ee).

The Coccyx

Three to five (usually four) tiny **coccygeal vertebrae** (Co1 to Co4 or Co5) fuse by the age of 20 to 30 years to form the **coccyx**⁴⁰ (COC-six) (fig. 8.28), colloquially called the tailbone. Although it is indeed the vestige of an ancestral tail, it is not entirely useless; it provides attachment for the muscles of the pelvic floor. Vertebra Co1 has a pair of **horns** (**cornua**) that serve as attachment points for ligaments that bind the coccyx to the sacrum. The coccyx can be fractured by a difficult childbirth or a hard fall on the buttocks.

8.3e The Thoracic Cage

The **thoracic cage** (fig. 8.29) consists of the thoracic vertebrae, sternum, and ribs. It forms a roughly conical enclosure for the lungs and heart and provides attachment for the pectoral girdle and upper limb. It has a broad base and a somewhat narrower superior apex. Its inferior border is the arc of the lower ribs, called the **costal margin**. The cage protects not only the thoracic organs but also the spleen, most of the liver and stomach, and to some extent the kidneys. Most important is its role in

breathing; it is rhythmically expanded by the respiratory muscles to create a vacuum that draws air into the lungs, and then compressed to expel air.

The Sternum

The **sternum** (breastbone) is a bony plate anterior to the heart. It is subdivided into three regions: the manubrium, body, and xiphoid process. The **manubrium**⁴¹ (ma-NOO-bree-um) is the broad superior portion, shaped like the knot of a necktie. It lies at the level of vertebrae T3 to T4. It has a median **suprasternal (jugular) notch**, which you can easily palpate between your clavicles (collarbones), and right and left **clavicular notches** where it articulates with the clavicles. These articulations are called the **sternoclavicular joints**. The dagger-shaped **body**, or **gladiolus**,⁴² is the longest part of the sternum, lying at the level of vertebrae T5 through T9. It joins the manubrium at the **sternal angle**, which can be palpated as a transverse ridge at the point where the sternum projects farthest forward. In some people, however, the angle is rounded or concave. The second rib attaches here, making the sternal angle a useful landmark for counting ribs by palpation. The manubrium and body have scalloped lateral margins where cartilages of the ribs are attached. At the inferior end (vertebral level T10 to T11) is a small, pointed **xiphoid**⁴³ **process** (ZIF-oyd) that provides attachment for some of the abdominal muscles. In cardiopulmonary resuscitation, improperly performed chest compressions can drive the xiphoid process into the liver and cause a fatal hemorrhage.

⁴³xipho = sword; oid = resembling

FIGURE 8.29 The Thoracic Cage and Pectoral Girdle (Anterior View). **APR**

The Ribs

There are normally 12 pairs of **ribs**, with no difference between the sexes (despite a popular belief). Studies have found that as much as 6% of the population have variations, from one rib fewer than usual to as many as 15 pairs. Each is attached at its posterior (proximal) end to the vertebral column, and most of them are also attached at the anterior (distal) end to the sternum. The anterior attachment is by way of a long strip of hyaline cartilage called the **costal cartilage** (COSS-tul). The moderately flexible costal cartilages allow ribs the freedom of movement necessary for breathing.

The ribs are numbered 1 to 12 from the top down. As a rule, they increase in length from 1 through 7 and become progressively smaller again through rib 12. They are increasingly oblique (slanted) in orientation from 1 through 9, then less so from 10 through 12. They also differ in their individual structure and attachments at different levels of the thoracic cage, so we will examine them in order as we descend the chest, taking note of their universal characteristics as well as their individual variations.

Rib 1 is peculiar. On an articulated skeleton, look for its vertebral attachment just below the base of the neck; much of this rib lies above the level of the clavicle (fig. 8.29). It is a short, flat, C-shaped plate of bone (fig. 8.30a). At the vertebral end, it exhibits a knobby **head** that articulates with the body of vertebra T1.

Immediately distal to the head, the rib narrows to a **neck** and then widens again to form a rough area called the **tubercle**. This is its point of attachment to the transverse costal facet of the same vertebra. Beyond the tubercle, the rib flattens and widens into a gently sloping bladelike **shaft (body)**. The shaft ends distally in a squared-off, rough area. In the living individual, the costal cartilage begins here and spans the rest of the distance to the upper sternum.

Ribs 2 through 7 present a more typical appearance (fig. 8.30b). At the proximal end, each exhibits a head, neck, and tubercle. The head is wedge-shaped and inserts between two vertebrae. Each margin of the wedge has a smooth surface called an *articular facet*. The **superior articular facet** joins the inferior costal facet of the vertebra above; the **inferior articular facet** joins the superior costal facet of vertebra below. The tubercle of the rib articulates with the transverse costal facet of each same-numbered vertebra. **Figure 8.31** details the rib–vertebra attachments typical of this region of the rib cage.

Beyond the tubercle, each rib makes a sharp curve around the side of the chest and then progresses anteriorly to approach the sternum (see fig. 8.29). The curve is called the **angle** of the rib, and the rest of the bony blade distal to it is the shaft. The inferior margin of the shaft has a **costal groove** that marks the path of the intercostal blood vessels and nerve. Each of these ribs, like rib 1,

FIGURE 8.30 Anatomy of the Ribs. (a) Rib 1 (superior view) is an atypical flat plate. (b) Typical features of ribs 2 to 10. (c) Appearance of the floating ribs, 11 and 12.

ends in a blunt, rough area where the costal cartilage begins. Each has its own costal cartilage connecting it to the sternum; because of this feature, ribs 1 through 7 are called **true (vertebrosternal) ribs**.

Ribs 8 through 12 are called **false ribs** because they lack independent cartilaginous connections to the sternum. Ribs 8 through 10 are also called **vertebrochondral ribs**; their costal cartilages sweep upward and end on the costal cartilage of rib 7 (see fig. 8.29). Rib 10 also differs from 2 through 9 in that it attaches to the body of a single vertebra (T10) rather than between vertebrae. Thus, vertebra T10 has a complete costal facet on its body for rib 10.

Ribs 11 and 12 are again unusual; they are called **floating (vertebral) ribs** because they have no direct or indirect connection to the sternum at all (fig. 8.30c). Posteriorly, they articulate with the bodies of vertebrae T11 and T12, but they don't have tubercles and don't attach to the transverse processes of the vertebrae. Those two vertebrae therefore have no transverse costal facets. At the distal end, these two relatively small, delicate ribs taper to a point and are capped by a small cartilaginous tip; there is no cartilaginous connection to the sternum or to any of the higher costal cartilages. The ribs are merely embedded in lumbar muscle at this end. In people of Japanese and some other ancestries, rib 10 is also usually floating. **Table 8.4**

FIGURE 8.31 Articulation of Rib 6 with Vertebrae T5 and T6. (a) Anterior view. Note the relationship of the articular facets of the rib with the costal facets of the two vertebrae. (b) Superior view. Note that the rib articulates with a vertebra at two points: the costal facet on the vertebral body and the transverse costal facet on the transverse process.

summarizes variations in the naming of ribs according to their sternal attachments.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- Discuss the contribution of the intervertebral discs to the length and flexibility of the spine.
- Construct a three-column table headed C4, T4, and L4. In each column, list all anatomical features that would distinguish that vertebra from the other two.
- Name the three parts of the sternum. How many ribs attach (directly or indirectly) to each part?
- Describe how rib 5 articulates with the spine. How do ribs 1 and 12 differ from this and from each other in their modes of articulation?
- Distinguish between true, false, and floating ribs. Which ribs fall into each category?
- Name the three divisions of the sternum and list the sternal features that can be palpated on a living person.

TABLE 8.4 Articularations of the Ribs

Rib	Type	Costal Cartilage
1	True, vertebrosteral	Individual
2	True, vertebrosteral	Individual
3	True, vertebrosteral	Individual
4	True, vertebrosteral	Individual
5	True, vertebrosteral	Individual
6	True, vertebrosteral	Individual
7	True, vertebrosteral	Individual
8	False, vertebrochondral	Shared with rib 7
9	False, vertebrochondral	Shared with rib 7
10	False, vertebrochondral	Shared with rib 7
11	False, floating, vertebral	None
12	False, floating, vertebral	None

8.4 The Pectoral Girdle and Upper Limb

Expected Learning Outcome

When you have completed this section, you should be able to

- identify and describe the features of the clavicle, scapula, humerus, radius, ulna, and bones of the wrist and hand.

8.4a The Pectoral Girdle

The **pectoral girdle** (shoulder girdle) supports the arm and links it to the axial skeleton. It consists of two bones on each side of the body: the *clavicle* (collarbone) and *scapula* (shoulder blade). The medial end of the clavicle articulates with the sternum at the **sternoclavicular joint**, and its lateral end articulates with the scapula at the **acromioclavicular joint** (see fig. 8.29). The scapula also articulates with the humerus at the **glenohumeral joint**. These are loose attachments that result in a shoulder far more mobile than that of most other mammals, but they also make the shoulder joint easy to dislocate.

▶▶▶ APPLY WHAT YOU KNOW

How is the unusual mobility of the human shoulder joint related to the habitat of our primate ancestors?

The Clavicle

The **clavicle**⁴⁴ (fig. 8.32) is slightly S-shaped, somewhat flattened from the upper to lower surface, and easily seen and palpated on

FIGURE 8.32 The Right Clavicle. (a) Superior view. (b) Inferior view. **APR**

the upper thorax (see atlas B, fig. B.1b). The superior surface is relatively smooth and rounded, whereas the inferior surface is flatter and marked by grooves and ridges for muscle attachment. The medial **sternal end** has a rounded, hammerlike head, and the lateral **acromial end** is markedly flattened. Near the acromial end is a small tuberosity called the **conoid tubercle**—a ligament attachment that faces posteriorly and slightly downward.

The clavicle braces the shoulder, keeping the upper limb away from the midline of the body, and is an attachment for some of the muscles of head movement (sternocleidomastoid and trapezius). It also transfers force from the arm to the axial region of the body, as when doing pushups. It is thickened in people who do heavy manual labor, and in right-handed people, the right clavicle is usually stronger and shorter than the left because of the workload placed on it. Without the clavicles, the pectoralis major muscles would pull the shoulders forward and medially—which indeed happens when a clavicle is fractured. The clavicle is one of the most commonly fractured bones in the body because it is so close to the surface and because people often reach out with their arms to break a fall or brace themselves in a vehicular collision.

The Scapula

The **scapula**⁴⁵ (fig. 8.33), named for its resemblance to a spade or shovel, is a triangular plate that posteriorly overlies ribs 2 through 7. Its only direct attachment to the thorax is by muscles; it glides across the rib cage as the arm and shoulder move. The three sides of the triangle are called the **superior**, **medial (vertebral)**, and **lateral (axillary) borders**, and its three angles are the **superior**, **inferior**, and **lateral angles**. A conspicuous **suprascapular notch** in the superior border provides passage for a nerve. The broad anterior surface of the scapula, called the **subscapular fossa**, is slightly concave and relatively featureless. The posterior surface has a transverse ridge called the **spine**, a deep indentation superior

⁴⁴clav = hammer, club, key; icle = little

⁴⁵scap = spade, shovel; ula = little

FIGURE 8.33 The Right Scapula. (a) Anterior view. (b) Posterior view. **APR**

to the spine called the **supraspinous fossa**, and a broad surface inferior to it called the **infraspinous fossa**.⁴⁶

The most complex region of the scapula is its lateral angle, which has three main features:

1. The **acromion**⁴⁷ (ah-CRO-me-on) is a platelike extension of the scapular spine that forms the apex of the shoulder. It articulates with the clavicle, which forms the sole bridge from the appendicular to the axial skeleton.
2. The **coracoid**⁴⁸ **process** (COR-uh-coyd) is named for a vague resemblance to a crow's beak, but is shaped more like a bent finger; it provides attachment for tendons of the *biceps brachii* and other muscles of the arm.
3. The **glenoid**⁴⁹ **cavity** (GLEN-oyd) is a shallow socket that articulates with the head of the humerus, forming the glenohumeral joint. The anatomy of this joint is detailed in chapter 9.

8.4b The Upper Limb

Each upper limb contains 30 bones distributed in the following three limb segments:

1. The arm proper (**brachial region** or **brachium**⁵⁰ [BRAY-kee-um]) extends from shoulder to elbow. It contains only one bone, the *humerus*.

2. The forearm (**antebrachial region** or **antebrachium**⁵¹) extends from elbow to wrist and contains two bones: the *radius* and *ulna*. In anatomical position, these bones are parallel and the radius is lateral to the ulna.
3. The hand consists of the **carpal**⁵² **region**, with 8 small carpal bones arranged in two rows in the base of the hand; the **metacarpal region** in the palm, with 5 bones; and the fingers (**digits**), with 14 bones. The hands alone contain 54 of the 206 bones in the body—over one-quarter of the skeleton by bone count.

Note that what we colloquially call the wrist—the narrow region where one may wear a bracelet or wristwatch—is not what anatomists call the carpal region: the thick, fleshy base of the hand proximal to the hollow of the palm.

The Humerus

The **humerus** has a hemispherical **head** that articulates with the glenoid cavity of the scapula (**fig. 8.34**). The smooth surface of the head (covered with articular cartilage in the living state) is bordered by a groove called the **anatomical neck**. Other prominent features of the proximal end are muscle attachments called the **greater** and **lesser tubercles** and an **intertubercular sulcus** between them that accommodates a tendon of the biceps muscle. The **surgical neck**, a common fracture site, is a narrowing of the

⁴⁶*supra* = above; *infra* = below

⁴⁷*acr* = extremity, point, apex; *omi* = shoulder

⁴⁸*corac* = crow; *oid* = resembling

⁴⁹*glen* = pit, socket; *oid* = resembling

⁵⁰*brachi* = arm

⁵¹*ante* = before

⁵²*carp* = wrist

bone just distal to the tubercles, at the transition from the head to the shaft. The shaft has a rough area called the **deltoid tuberosity** on its lateral surface. This is an insertion for the *deltoid muscle* of the shoulder.

The distal end of the humerus has two smooth condyles. The lateral one, called the **capitulum**⁵³ (ca-PIT-you-lum), is shaped like a wide tire and articulates with the radius. The medial one, called the **trochlea**⁵⁴ (TROCK-lee-uh), is pulleylike and articulates with the ulna. Immediately proximal to these condyles, the humerus flares out to form two bony processes, the **lateral** and **medial epicondyles**, which are the bumps you can palpate at the widest point of your elbow. The medial epicondyle protects the *ulnar nerve*, which passes close to the surface across the back of the elbow. This epicondyle is popularly known as the “funny bone” because striking the elbow on the edge of a table stimulates the ulnar nerve and produces a sharp tingling sensation. Immediately proximal to the epicondyles, the margins

of the humerus are called the **lateral** and **medial supracondylar ridges**. These are attachments for certain forearm muscles described in chapter 10.

The distal end of the humerus also shows three deep pits: two anterior and one posterior. The posterior pit, called the **olecranon fossa** (oh-LEC-ruh-non), accommodates a process of the ulna called the *olecranon* when the elbow is extended. On the anterior surface, a medial pit called the **coronoid fossa** accommodates the *coronoid process* of the ulna when the forearm is flexed. The lateral pit is the **radial fossa**, named for the nearby head of the radius.

The Radius

The **radius** has a distinctive discoidal **head** at its proximal end (fig. 8.35). When the forearm is rotated so the palm turns forward and back, the circular superior surface of this disc spins on the capitulum of the humerus, and the edge of the disc spins on the radial notch of the ulna. Immediately distal to the head, the radius has a narrower **neck** and then widens to a rough prominence, the **radial tuberosity**, on its medial surface. The distal tendon of the biceps muscle terminates on this tuberosity.

⁵³*capit* = head; *ulum* = little

⁵⁴*troch* = wheel, pulley

FIGURE 8.34 The Right Humerus. (a) Anterior view. (b) Posterior view. **APR**

FIGURE 8.35 The Right Radius and Ulna. (a) Anterior view. (b) Posterior view. **APR**

The distal end of the radius has the following features, from lateral to medial:

1. a bony point, the **styloid process**, which can be palpated proximal to the thumb;
2. two shallow depressions (articular facets) that articulate with the scaphoid and lunate bones of the wrist; and
3. the **ulnar notch**, which articulates with the end of the ulna.

The Ulna

At the proximal end of the **ulna** (fig. 8.35) is a deep, C-shaped **trochlear notch** that wraps around the trochlea of the humerus. The posterior side of this notch is formed by a prominent **olecranon**—the bony point where you rest your elbow on a table. The anterior side is formed by a less prominent **coronoid process**. Laterally, the head of the ulna has a less conspicuous **radial notch**, which accommodates the edge of the head of the radius. At the distal end (**head**) of the ulna is a medial **styloid process**. The bony lumps you can palpate on each side of your wrist are the styloid processes of the radius and ulna. Notice that the “heads” of the radius and ulna are at opposite ends—the proximal end of the radius but distal end of the ulna.

The radius and ulna are attached along their shafts by a ligament called the **interosseous membrane (IM)** (IN-tur-OSS-ee-us), which is attached to an angular ridge called the **interosseous margin** on each bone. Most fibers of the IM are oriented obliquely, slanting upward from the ulna to the radius. If you do pushups or you lean forward on a table supporting your weight on your hands, about 80% of the force is borne by the radius. This tenses the IM, which pulls the ulna upward and transfers some of this force through the ulna to the humerus. The IM thereby enables two elbow joints (humeroradial and humeroulnar) to share the load; this reduces the wear and tear that one joint would otherwise have to bear alone. The IM also serves as an attachment for several forearm muscles.

The Carpal Bones

The **carpal bones** are arranged in two rows of four bones each (fig. 8.36). The short carpal bones allow movements of the hand from side to side and anterior to posterior. The carpal bones of the proximal row, starting at the lateral (thumb) side, are the **scaphoid**, **lunate**, **triquetrum** (tri-QUEE-trum), and **pisiform** (PY-sih-form)—Latin for boat-, moon-, triangle-, and pea-shaped, respectively. Unlike the other carpal bones, the pisiform is a sesamoid bone; it’s not present at birth but develops around the age of 9 to 12 years within the tendon of the *flexor carpi ulnaris muscle*.

The bones of the distal row, again starting on the lateral side, are the **trapezium**,⁵⁵ **trapezoid**, **capitate**,⁵⁶ and **hamate**.⁵⁷ The

hamate can be recognized by a prominent hook called the **hamulus** on the palmar side (fig. 8.36b). The hamulus is an attachment for the *flexor retinaculum*, a fibrous sheet in the wrist that covers the carpal tunnel (see fig. 10.31).

The Metacarpal Bones

The **metacarpal**⁵⁸ bones span the palmar region of the hand. Metacarpal I is located proximal to the base of the thumb and metacarpal V proximal to the base of the little finger. On a skeleton, the metacarpal bones look like extensions of the fingers, making the fingers seem much longer than they really are. The proximal end of a metacarpal bone is called the **base**, the shaft is called the **body**, and the distal end is called the **head**. The heads of the metacarpal bones form the proximal row of knuckles when you clench your fist.

The Phalanges

The bones of the fingers are called **phalanges** (fah-LAN-jeez)—in the singular, *phalanx* (FAY-lanks). There are two phalanges in the thumb and three in each of the other fingers. Phalanges are identified by roman numerals preceded by *proximal*, *middle*, and *distal*. For example, proximal phalanx I is in the basal segment of the thumb (the first segment beyond the web between the thumb and palm); the left proximal phalanx IV is where people commonly wear wedding rings; and distal phalanx V forms the tip of the little finger. The three parts of a phalanx are the same as in a metacarpal: base, body, and head. The anterior (palmar) surface of a phalanx is slightly concave from end to end and flattened from side to side; the posterior surface is rounder and slightly convex.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

15. Describe how to distinguish the medial and lateral ends of the clavicle from each other, and how to distinguish its superior and inferior surfaces.
16. Name the three fossae of the scapula and describe the location of each.
17. What three bones meet at the elbow? Identify the fossae, articular surfaces, and processes of this joint and state to which bone each of these features belongs.
18. Name the four carpal bones of the proximal row from lateral to medial, then the four bones of the distal row in the same order.
19. Name the four long bones from the tip of the little finger to the base of the hand.

⁵⁵*trapez* = table, grinding surface

⁵⁶*capit* = head; *ate* = possessing

⁵⁷*ham* = hook; *ate* = possessing

⁵⁸*meta* = beyond; *carp* = wrist

8.5 The Pelvic Girdle and Lower Limb

Expected Learning Outcomes

When you have completed this section, you should be able to

- identify and describe the features of the pelvic girdle, femur, patella, tibia, fibula, and bones of the foot; and
- compare the anatomy of the male and female pelvic girdles and explain the functional significance of the differences.

8.5a The Pelvic Girdle

The terms *pelvis* and *pelvic girdle* are used in contradictory ways by various anatomical authorities. Here we will follow the practice

of *Gray's Anatomy* and the *Terminologia Anatomica* in considering the **pelvic girdle** to consist of a complete ring composed of three bones (**fig. 8.37**)—two **hip (coxal) bones** and the sacrum (which, as you know, is also part of the vertebral column). The hip bones are also frequently called the *ossa coxae*⁵⁹ (OS-sa COC-see). The **pelvis**⁶⁰ is a bowl-shaped structure composed of these bones as well as the ligaments and muscles that line the pelvic cavity and form its floor. The pelvic girdle supports the trunk on the lower limbs and encloses and protects the viscera of the pelvic cavity—mainly the lower colon, urinary bladder, and internal reproductive organs.

Each hip bone is joined to the vertebral column at one point, the sacroiliac joint, where its ear-shaped **auricular surface** matches the auricular surface of the sacrum. The two hip bones articulate with each other on the anterior side of the pelvis, where they are joined by a pad of fibrocartilage called the **interpubic**

⁵⁹*os* = bone; *coxae* = of the hip

⁶⁰*pelv* = basin, bowl

FIGURE 8.37 The Pelvic Girdle. (a) Anterosuperior view, tilted slightly toward the viewer to show the base of the sacrum and the pelvic inlet. (b) Median section, to show the greater and lesser pelvis and the pelvic inlet and outlet. **APR**

disc. The disc and the adjacent region of each pubic bone constitute the **pubic symphysis**,⁶¹ which can be palpated as a hard prominence immediately above the genitalia.

The pelvis is divided into the broad **greater (false) pelvis** between the flare of the hips and the narrower **lesser (true) pelvis** below. The two are separated by a round margin called the **pelvic brim**. The opening circumscribed by the brim is called the **pelvic inlet**—an entry into the lesser pelvis through which an infant's head passes during birth. The lower margin of the lesser pelvis is called the **pelvic outlet**, through which the infant exits the pelvis at the conclusion of birth.

The hip bones have three distinctive features that will serve as landmarks for further description. These are the **iliac**⁶² **crest** (superior crest of the hip); **acetabulum**⁶³ (ASS-eh-TAB-you-lum) (the hip socket—named for its resemblance to vinegar cups used on ancient Roman dining tables); and **obturator**⁶⁴ **foramen** (a large round-to-triangular hole below the acetabulum, closed by a ligament called the *obturator membrane* in living persons).

The adult hip bone forms by the fusion of three childhood bones called the *ilium* (ILL-ee-um), *ischium* (ISS-kee-um), and *pubis* (PEW-biss), identified by color in **figure 8.38**. These three centers don't completely fuse into a single hip bone until the age of 15 to 25 years. The largest of the three is the **ilium**, which extends from the iliac crest to the center of the acetabulum. The iliac crest extends from an anterior point or angle called the **anterior superior iliac spine** to a sharp posterior angle called the **posterior superior iliac spine**. In a lean person, the anterior superior spines form visible anterior protrusions at a point where the front pockets usually open on a pair of pants, and the posterior superior spines are sometimes marked by dimples above the buttocks where connective tissue attached to the spines pulls inward on the skin (see atlas B, fig. B.15). The latter is a genetic trait like cheek dimples.

Below the superior spines are the **anterior** and **posterior inferior iliac spines**. Below the latter is a deep **greater sciatic notch** (sy-AT-ic), named for the thick sciatic nerve that passes through it and continues down the posterior side of the thigh.

The posterolateral surface of the ilium is relatively rough-textured because it serves for attachment of several muscles of the buttocks and thighs. The anteromedial surface, by contrast, is the smooth, slightly concave **iliac fossa**, covered in the living body by the broad *iliacus muscle*. Medially, the ilium exhibits an auricular surface that matches the one on the sacrum, so that the two bones form the sacroiliac (SI) joint.

The **ischium** is the inferoposterior portion of the hip bone. Its heavy **body** is marked with a prominent **ischial spine**. Inferior to

FIGURE 8.38 The Right Hip Bone. (a) Lateral view. (b) Medial view. The three childhood bones that fuse to form the adult hip bone are identified by color according to the key. **APR**

⁶¹sym = together; physis = growth

⁶²ili = flank, loin; ac = pertaining to

⁶³acetabulum = vinegar cup

⁶⁴obtur = to close, stop up; ator = that which

the spine is a slight indentation, the **lesser sciatic notch**, and then the thick, rough-surfaced **ischial tuberosity**, which supports your body when you are sitting. The tuberosity can be palpated by sitting on your fingers. The **ramus** of the ischium joins the inferior ramus of the pubis anteriorly.

The **pubis (pubic bone)** is the most anterior portion of the hip bone. In anatomical position, it is nearly horizontal and serves as a platform for the urinary bladder. It has a **superior** and **inferior ramus** and a triangular **body**. The body of one pubis meets the body of the other at the pubic symphysis. The pubis and ischium encircle the obturator foramen. The pubis is often fractured when the pelvis is subjected to violent anteroposterior compression, as in vehicular seat-belt injuries.

The pelvis is the most *sexually dimorphic* part of the skeleton—that is, the one whose anatomy most differs between the sexes. In identifying the sex of skeletal remains, forensic scientists focus especially on the pelvis but on many other bones as well. The average male pelvis is more robust (heavier and thicker) than the female's owing to the forces exerted on the bones by stronger muscles. The female pelvis is adapted to the needs of pregnancy and childbirth. It is wider and shallower and has a larger pelvic inlet and outlet for passage of the infant's head. **Table 8.5** and **figure 8.39** summarize the most useful features of the pelvis in sex identification.

8.5b The Lower Limb

The number and arrangement of bones in the lower limb are similar to those of the upper limb. In the lower limb, however, they are adapted for weight bearing and locomotion and are therefore shaped and articulated differently. The femur and tibia are essentially pillars for supporting the weight of the body. Each lower limb has 30 bones distributed in the following three segments.

1. The thigh (**femoral region**) extends from hip to knee and contains the *femur*. The *patella* (kneecap) is a sesamoid bone at the junction of the femoral and crural regions.
2. The leg proper (**crural region**) extends from knee to ankle and contains two bones, the medial *tibia* and lateral *fibula*.
3. The foot consists of the **tarsal region**, with 7 tarsal bones extending from the heel to the midpoint of the foot arch; **metatarsal region**, with 5 bones extending from there to the “balls” of the feet just proximal to the toes; and toes (**digits**), with 14 bones. The feet and hands together contain more than half of all the body's bones (106 of the total 206).

The Femur

The **femur** (FEE-mur) is the longest and strongest bone of the body, measuring about one-quarter of one's height (**fig. 8.40**). It has a hemispherical head that articulates with the acetabulum of the pelvis, forming a quintessential *ball-and-socket joint*. A

ligament extends from the acetabulum to a pit, the **fovea capitis**⁶⁵ (FOE-vee-uh CAP-ih-tiss), in the head of the femur. Distal to the head is a constricted **neck** and then two massive, rough processes called the **greater** and **lesser trochanters**⁶⁶ (tro-CAN-turs), which are insertions for the powerful muscles of the hip. The trochanters are connected on the posterior side by a thick oblique ridge of bone, the **intertrochanteric crest**, and on the anterior side by a more delicate **intertrochanteric line**.

The primary feature of the shaft is a posterior ridge called the **linea aspera**⁶⁷ (LIN-ee-uh ASS-peh-ruh) at its midpoint. At its upper end, the linea aspera forks into a medial **spiral (pectineal) line** and a lateral **gluteal tuberosity**. The gluteal tuberosity is a rough ridge (sometimes a depression) that serves for attachment of the powerful *gluteus maximus* muscle of the buttock. At its lower end, the linea aspera forks into **medial** and **lateral supracondylar lines**, which continue down to the respective epicondyles.

The **medial** and **lateral epicondyles** are the widest points of the femur, easily palpated at the knee. These and the supracondylar lines are attachments for certain thigh and leg muscles and knee ligaments. At the distal end of the femur are two smooth round surfaces of the knee joint, the **medial** and **lateral condyles**, separated by a groove called the **intercondylar fossa** (IN-tur-CON-dih-lur). During knee flexion and extension, the condyles rock on the superior surface of the tibia. On the anterior side of the femur, a smooth medial depression called the **patellar surface** articulates with the patella. On the posterior side is a flat or slightly depressed area called the **popliteal surface**.

The Patella

The **patella**,⁶⁸ or kneecap (**fig. 8.40**), is a roughly triangular sesamoid bone embedded in the tendon of the knee. It is cartilaginous at birth and ossifies at 3 to 6 years of age. It has a broad superior **base**, a pointed inferior **apex**, and a pair of shallow **articular facets** on its posterior surface where it articulates with the femur. The lateral facet is usually larger than the medial. The *quadriceps femoris tendon* extends from the anterior *quadriceps femoris muscle* of the thigh to the patella, and it continues as the *patellar ligament* from the patella to the tibia. This is a change in terminology more than a change in structure or function, as a tendon connects muscle to bone and a ligament connects bone to bone. Because of the way the quadriceps tendon loops over the patella, the patella acts like a pulley, modifying the direction of pull by the quadriceps muscle. This improves its efficiency in extending the knee, hence the efficiency of walking and running.

The Tibia

The leg has two bones: a thick strong tibia (TIB-ee-uh) on the medial side and a slender fibula (FIB-you-luh) on the lateral side

⁶⁵*fovea* = pit; *capitis* = of the head

⁶⁶*trochanter* = to run

⁶⁷*linea* = line; *asper* = rough

⁶⁸*pat* = pan; *ella* = little

TABLE 8.5 Comparison of the Male and Female Pelvic Girdles

Feature	Male	Female
General appearance	More massive; rougher; heavier processes	Less massive; smoother; more delicate processes
Tilt	Upper end of pelvis relatively vertical	Upper end of pelvis tilted forward
Depth of greater pelvis	Deeper; ilium projects farther above sacroiliac joint	Shallower; ilium does not project as far above sacroiliac joint
Width of greater pelvis	Hips less flared; anterior superior spines closer together	Hips more flared; anterior superior spines farther apart
Pelvic inlet	Heart-shaped	Round or oval
Pelvic outlet	Smaller	Larger
Subpubic angle	Narrower, usually 90° or less	Wider, usually 100° or more
Pubic symphysis	Taller	Shorter
Body of pubis	More triangular	More rectangular
Greater sciatic notch	Narrower	Wider
Obturator foramen	Rounder	More oval to triangular
Acetabulum	Larger, faces more laterally	Smaller, faces slightly anteriorly
Sacrum	Narrower and deeper	Wider and shallower
Coccyx	Less movable; more vertical	More movable; tilted posteriorly

FIGURE 8.39 Comparison of the Male and Female Pelvic Girdles. (a) Male, medial view. (b) Male, anterior view. (c) Female, medial view. (d) Female, anterior view. Compare with table 8.5.

FIGURE 8.40 The Right Femur and Patella.

(a) Anterior view.

(b) Posterior view. **APR**

(fig. 8.41). The **tibia** is the only weight-bearing bone of the crural region. Its broad superior head has two fairly flat articular surfaces, the **medial** and **lateral condyles**, separated by a ridge called the **intercondylar eminence**. This superior surface of the tibia is often called the **tibial plateau**. The condyles of the tibia articulate with those of the femur. The rough anterior surface of the upper tibia, the **tibial tuberosity**, can be palpated just below the patella. This is an attachment for the powerful thigh muscles that extend (straighten) the knee. Distal to this, the shaft has a sharply angular **anterior border**, which can be palpated in the shin. At the ankle, just above the rim of a standard dress shoe, you can palpate a prominent bony knob on each side. These are the **medial** and **lateral malleoli**⁶⁹ (MAL-ee-OH-lie). The medial malleolus is part of the tibia, and the lateral malleolus is the part of the fibula.

The Fibula

The **fibula**⁷⁰ (fig. 8.41) is a slender lateral strut that helps to stabilize the ankle. It doesn't bear any of the body's weight; indeed, orthopedic surgeons sometimes remove part of the fibula and use it to replace damaged or missing bone elsewhere in the body. The fibula is somewhat thicker and broader at its proximal end, the **head**, than at the distal end. The point of the head is called the **apex**. The distal expansion is the lateral malleolus. Like the radius and ulna, the tibia and fibula are joined by an interosseous membrane along their shafts, and by shorter ligaments at the superior and inferior ends where the fibular head and apex contact the tibia.

⁶⁹malle = hammer; olus = little

⁷⁰fibula = little pin or clasp; from a garment pin in ancient Greece and Rome

FIGURE 8.41 The Right Tibia and Fibula.
(a) Anterior view. (b) Posterior view. **APR**

The Ankle and Foot

The **tarsal bones** of the ankle are arranged in proximal and distal groups somewhat like the carpal bones of the wrist (**fig. 8.42**). Because of the load-bearing role of the ankle, however, their shapes and arrangement are conspicuously different from those of the carpal bones, and they are fully integrated into the structure of the foot. The largest tarsal bone is the **calcaneus**⁷¹ (cal-CAY-nee-us), the bone of the heel. Its posterior end is the point of attachment for the **calcaneal (Achilles) tendon** from the calf muscles. The second-largest tarsal bone, and the most superior, is the **talus**. It has three articular surfaces: an inferoposterior one that articulates with the calcaneus, a superior **trochlear surface** that articulates with the tibia, and an anterior surface that articulates with a short, wide tarsal bone called the **navicular**.⁷² The talus, calcaneus, and navicular are considered the proximal row of tarsal bones.

As with the colloquial versus anatomical meaning of *wrist*, the two meanings of *ankle* differ. Colloquially, most of us think of it as the narrow point where one may wear an ankle bracelet, above the malleoli. Anatomically, though, it means the more distal region where the tibia articulates with the talus.

The distal group forms a row of four bones. Proceeding from the medial to lateral, these are the **medial**, **intermediate**, and

lateral cuneiforms⁷³ (cue-NEE-ih-forms) and the **cuboid**. The cuboid is the largest.

▶▶▶ APPLY WHAT YOU KNOW

The upper and lower limbs each contain 30 bones, yet we have 8 carpal bones in the upper limb and only 7 tarsal bones in the lower limb. What makes up the difference in the lower limb?

The remaining bones of the foot are similar in arrangement and name to those of the hand. The proximal **metatarsal**⁷⁴ bones are similar to the metacarpals. They are **metatarsals I** through **V** from medial to lateral, metatarsal I being proximal to the great toe. Metatarsals I to III articulate with the first through third cuneiforms; metatarsals IV and V both articulate with the cuboid.

Bones of the toes, like those of the fingers, are called **phalanges**. The great toe contains only two bones, the proximal and distal phalanx I. The other toes each contain a proximal, middle, and distal phalanx, and are numbered II through V from medial to lateral. Thus middle phalanx V, for example, would be the middle bone of the smallest toe. The metatarsal and phalangeal bones each have a base, body, and head, like the bones of the hand. All of them, especially the phalanges, are slightly concave on the inferior (plantar) side.

⁷¹calc = stone, chalk

⁷²navi = boat; cul = little; ar = like

⁷³cunei = wedge; form = in the shape of

⁷⁴meta = beyond; tars = ankle

FIGURE 8.42 The Right Foot. (a) Superior (dorsal) view. (b) Inferior (plantar) view. (c) Medial view. **APR**

? Contrast the tarsal bones with the carpal bones. Which ones are similar in location? Which ones are different?

Note that roman numeral I represents the *medial* group of bones in the foot but the *lateral* group in the hand. In both cases, however, it refers to the largest digit of the limb. The reason for the difference between the hand and foot lies in a rotation of the limbs that occurs in the seventh week of embryonic development. Early that week, the limbs extend anteriorly from the body, the foot is a paddlelike *foot plate*, and the *hand plate* is also more or less paddlelike with the finger buds showing early separation (**fig. 8.43a**). The future thumb and great toe are both directed superiorly, and the future palms and soles face each other medially. But then each limb rotates about 90° in opposite directions. The

FIGURE 8.43 Embryonic Limb Rotation. (a) Rotation of the hands and feet in opposite directions in week 7. (b) Resulting orientation of hands and feet established by week 8.

FIGURE 8.44 Arches of the Foot. (a) Inferior (plantar) view. (b) X-ray of right foot, lateral view.

b: stockdevil/123RF

upper limb rotates laterally. To visualize this, hold your hands straight out in front of you with the palms facing each other as if you were about to clap. Then rotate your forearms so the thumbs face away from each other (laterally) and the palms face upward. The lower limbs rotate in the opposite direction, medially, so that the soles face downward and the great toes become medial. So even though the thumb and great toe (digit I of the hand and foot) start out facing in the same direction, these opposite rotations result in their being on opposite sides of the hand and foot (**fig. 8.43b**). This rotation also explains why the elbow flexes posteriorly and the knee flexes anteriorly, and why (as you will see in chapter 10) the muscles that flex the elbow are on the anterior side of the arm, whereas those that flex the knee are on the posterior side of the thigh.

The foot normally doesn't rest flat on the ground, but has three springy arches that distribute the body's weight between the heel and the heads of the metatarsal bones and absorb the stress of walking (**fig. 8.44**). The **medial longitudinal arch**, which essentially extends from heel to great toe, is formed from the calcaneus, talus, navicular, cuneiforms, and metatarsals I to III. It is normally well above the ground, as evidenced by the shape of a wet footprint. The **lateral longitudinal arch** extends from heel to little toe and includes the calcaneus, cuboid, and metatarsals IV and V. The **transverse arch** includes the cuboid, cuneiforms, and proximal heads of the metatarsal bones. These arches are held together by

short, strong ligaments. Excessive weight, repetitious stress, or congenital weakness of these ligaments can stretch them, resulting in *pes planus* (commonly called flat feet or fallen arches). This condition makes a person less tolerant of prolonged standing and walking. A comparison of the flat-footed apes with humans underscores the significance of the human foot arches (see Deeper Insight 8.4).

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

20. Name the bones of the adult pelvic girdle. What three bones of a child fuse to form the hip bone of an adult?
21. Name any four structures of the pelvis that you can palpate and describe where to palpate them.
22. Describe several ways in which the male and female pelvic girdles differ.
23. What parts of the femur are involved in the hip joint? What parts are involved in the knee joint?
24. Name the prominent knobs on each side of your ankle. What bones contribute to these structures?
25. Name all the bones that articulate with the talus and describe the location of each.

DEEPER INSIGHT 8.4

EVOLUTIONARY MEDICINE

Skeletal Adaptations for Bipedalism

Some mammals can stand, hop, or walk briefly on their hind legs, but humans are the only habitually bipedal mammals. Footprints preserved in a layer of volcanic ash in Tanzania indicate that hominids walked upright as early as 3.6 million years ago. This bipedal locomotion is possible only because of several adaptations of the human feet, legs, spine, and skull. These features are so distinctive that paleoanthropologists (those who study human fossil remains) can tell with considerable certainty whether a fossil species was able to walk upright.

As important as the hand has been to human evolution, the foot may be an even more significant adaptation. Unlike other mammals, humans support their entire body weight on two feet. While apes are flat-footed, humans have strong, springy foot arches that absorb shock as the body jostles up and down during walking and running. The tarsal bones are tightly articulated with one another, and the calcaneus is strongly developed. The great toe is less opposable than in most Old World monkeys and apes, but it's highly developed so it provides

the “toe-off” that pushes the body forward in the last phase of the stride (**fig. 8.45a**). For this reason, loss of the great toe has a more crippling effect than the loss of any other toe.

While the femurs of apes are nearly vertical, in humans they angle medially from hip to knee (**fig. 8.45b**). This places our knees closer together, beneath the body's center of gravity. We lock our knees when standing, allowing us to stand erect with little muscular effort. Apes cannot do this and cannot stand on two legs for very long without tiring—much as you would if you tried to maintain an erect posture with your knees slightly bent.

In apes and other quadrupedal (four-legged) mammals, the abdominal viscera are supported by the muscular abdominal wall. In humans, the viscera bear down on the floor of the pelvic cavity, and a bowl-shaped pelvis with an inturned floor is necessary to support their weight. This has resulted in a narrower pelvic outlet—a condition that creates pain and difficulty in giving birth to such large-brained infants.

(a) Foot

(b) Knee

(c) Gluteal muscles

FIGURE 8.45 Skeletal Adaptations for Bipedalism. Human adaptations for bipedalism are best understood by comparison to our close living relative, the chimpanzee, which is not adapted for a comfortable or sustained erect stance. See the text for the relevance of each comparison. (a) Foot. (b) Knee. (c) Gluteal muscles. (d) Pelvis. (e) Vertebral column. (f) Skull.

(figure continues)

The pain of childbirth seems unique to humans and, one could say, is a price we must pay for having both a large brain and a bipedal stance.

The largest muscle of the buttock, the *gluteus maximus*, serves in apes primarily as an abductor of the thigh—that is, it moves the leg laterally. In humans, however, the ilium has expanded posteriorly, so the *gluteus maximus* originates behind the hip joint. This changes the function of the muscle—instead of abducting the thigh, it pulls the thigh back in the second half of a stride (pulling back on your right thigh, for example, when your left foot is off the ground and swinging forward). Two other buttock muscles, the *gluteus medius* and *gluteus minimus*, extend laterally in humans from the surface of the ilium to the greater trochanter of the femur (**fig. 8.45c**). In walking, when one foot is lifted from the ground, these muscles subtly shift the body weight toward the other foot so we don't fall over. The actions of all three gluteal muscles, and the corresponding evolutionary remodeling of the pelvis, account for the smooth, efficient stride of a human as compared with the awkward, shuffling gait of a chimpanzee or gorilla when walking upright. The posterior growth of the ilium (**fig. 8.45d**) is the reason the greater sciatic notch is so deeply concave in humans.

The lumbar lordosis of the human spine allows for efficient bipedalism by shifting the body's center of gravity to the rear, above and slightly

behind the hip joint (**fig. 8.45e**). Because of their C-shaped spines, chimpanzees cannot stand as easily. Their center of gravity is anterior to the hip joint when they stand; they must make a constant muscular effort to keep from falling forward, and they fatigue quickly. Humans, by contrast, require little effort to keep their balance. Our australopithecine ancestors probably could travel all day with relatively little fatigue.

The human head is balanced on the vertebral column with the gaze directed forward. The cervical curvature of the spine and remodeling of the skull have made this possible. The foramen magnum has moved to a more inferior and anterior location, and the face is much flatter than an ape's face (**fig. 8.45f**), so there is less weight anterior to the occipital condyles. Being balanced on the spine, the head doesn't require strong muscular attachments to hold it erect.

The forelimbs of apes are longer than the hindlimbs; indeed, some species such as the orangutan and gibbons hold their long forelimbs over their heads when they walk on their hind legs. By contrast, our forelimbs are shorter than our hindlimbs and far less muscular than the forelimbs of apes. No longer needed for locomotion, our forelimbs have become better adapted for carrying objects, holding things closer to the eyes, and manipulating them more precisely.

FIGURE 8.45 Skeletal Adaptations for Bipedalism (*continued*).

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

8.1 Overview of the Skeleton

1. The difference between the axial and appendicular skeletons, and the bones in each category
2. The typical number of named bones in an adult; why this number differs in newborns and children; and why the number varies among adults
3. Sutural and sesamoid bones, and examples of the latter
4. Names of the various outgrowths, depressions, articular surfaces, cavities, and passages in bones

8.2 The Skull

1. The usual number of bones in the adult skull, and the collective name of the seams or joints that bind most of them together
2. Names and locations of the cavities that enclose the brain, nose, ears, and eyes, and of the paranasal sinuses
3. The collective function of the skull foramina; the location and function of the largest one, the foramen magnum
4. Major features of the cranium; the difference between its base and calvaria; the three cranial fossae and how they relate to brain anatomy
5. Names of the six cranial bones; which ones are solitary and which are bilaterally paired; and what distinguishes a cranial bone from a facial bone
6. The location and extent of the frontal bone; the suture that binds it to the parietal bones; and the locations of its supraorbital margin and foramen, glabella, frontal sinus, and diploe
7. The location and extent of the parietal bones; the suture formed where they meet the occipital bone and the one that separates the parietal bones from each other; and the locations of the parietal foramen and temporal lines
8. The location and extent of the temporal bones; the main suture that borders them; and the names and boundaries of their four major parts

9. The location and extent of the occipital bone, its basilar part, and the names and locations of its foramina, canals, and surface protrusions
10. The location and extent of the sphenoid bone; its wings, body, pterygoid plates, clinoid processes, and foramina; its relationships with the pituitary gland and nasal apertures
11. The location and extent of the ethmoid bone; its part in defining the nasal fossae; and the locations of its plates, foramina, air cells, and nasal conchae
12. Names of the eight facial bones; which ones are solitary and which are bilaterally paired
13. The location and extent of the maxilla; its foramina, alveoli, and alveolar and palatine processes; and the suture that joins the right and left maxillae
14. The location and extent of the palatine bones; their foramina; and their part in partially defining the walls of the nasal cavity and orbit
15. Structure of the palate, including the hard and soft regions and the contributions of the palatine processes and palatine bones
16. The location and extent of the zygomatic bones, and the temporal process and main foramen of each
17. The three parts of the zygomatic arch
18. The locations and structures of the tiny lacrimal and nasal bones
19. The inferior nasal concha and why it is distinguished from the superior and middle conchae
20. The location and extent of the vomer; contributions of the vomer and ethmoid bone to the nasal septum
21. Structure of the mandible, including the body, ramus, and angle; its two main processes and the notch between them; its foramina, symphysis, protuberance, and spines
22. The bones, and their specific features, that form the temporomandibular joint
23. The locations and names of the auditory ossicles; location and features of the hyoid bone; and functions of these bones
24. Names and locations of the fontanelles of the neonatal skull; why they exist; and how a child's skull changes between birth and 9 years of age

8.3 The Vertebral Column and Thoracic Cage

1. The number of vertebrae and intervertebral discs in the vertebral column (spine)
2. Four curvatures of the adult spine; which ones are present at birth; and when and how the others develop
3. Features of a typical vertebra
4. The five classes of vertebrae and the number of vertebrae in each class; the system of numbering them; and why the number of vertebrae in a child differs from the number at 30 years of age and beyond
5. Features that identify an isolated vertebra as cervical, thoracic, or lumbar
6. How the anatomy of the first two vertebrae (C1–C2) relates to movements of the head
7. How the anatomy of the thoracic vertebrae (T1–T12) relates to the articulations of the ribs
8. The structure and function of intervertebral discs; which vertebrae have discs between them and which ones do not
9. Anatomical features of the sacrum, including its foramina, crests, canal and hiatus, auricular surface and sacroiliac joint, promontory, and alae
10. Features of the coccyx
11. Components and general shape of the thoracic cage
12. Three main regions of the sternum; its notches and sternal angle
13. The number of ribs; which ones are true, false, and floating ribs
14. All features seen in most of the ribs
15. Which ribs differ from that typical anatomy, and how
16. How the ribs articulate with the vertebrae, including variations from the top to bottom of the rib cage

8.4 The Pectoral Girdle and Upper Limb

1. Names and locations of the 4 bones of the pectoral girdle and 30 bones of each upper limb
2. Names of the joints at which the humerus articulates with the scapula, the scapula with the clavicle, and the clavicle with the axial skeleton

STUDY GUIDE

- Features of the clavicle, including the sternal and acromial ends and conoid tubercle; function of the clavicles
- Features of the scapula, including its borders and angles, fossae, suprascapular notch, acromion, coracoid process, and glenoid cavity
- Names of the four regions of the upper limb and the bones contained in each
- Features of the humerus, including the head, necks, tubercles, intertubercular sulcus, deltoid tuberosity, capitulum, trochlea, epicondyles, supracondylar ridges, and three fossae
- Features of the radius, including the head, neck, radial tuberosity, styloid process, and ulnar notch
- Features of the ulna, including the trochlear and radial notches, coronoid and styloid processes, and olecranon; and the relationship of the radius and ulna to the interosseous membrane
- Names of the carpal bones, in order, from lateral to medial in the proximal row and lateral to medial in the distal row; the unusual structure of the hamate bone
- The system of naming and numbering the 5 metacarpal bones of the palmar region and 5 sets of phalanges in the digits; why there

are 5 digits but only 14 phalanges; the base, body, and head of all 19 metacarpals and phalanges

8.5 The Pelvic Girdle and Lower Limb

- Names and locations of the 3 bones of the pelvic girdle and 30 bones of each lower limb
- Names of the joints at which the lower limb articulates with the pelvic girdle and the pelvic girdle articulates with the axial skeleton
- The distinction between the pelvic girdle and pelvis
- Three childhood bones that fuse to form each adult hip (coxal) bone, and the boundaries of each on the hip bone
- Features of the hip (coxal) bones and pelvic girdle including the auricular surfaces; interpubic disc and pubic symphysis; greater and lesser pelvis; pelvic brim, inlet, and outlet; iliac crest; acetabulum; obturator foramen; four ischial spines; two sciatic notches; iliac fossa; and parts of the ischium and pubis
- Differences between the male and female pelvic girdles and the essential reason for these differences
- Names of the four regions of the lower limb and the bones contained in each

- Features of the femur, including the head, neck, fovea capitis, trochanters, intertrochanteric crest, gluteal tuberosity, condyles, intercondylar fossa, epicondyles, lines, and patellar and popliteal surfaces
- Features of the patella, including the base, apex, and articular facets
- Features of the tibia, including the lateral and medial condyles and intercondylar eminence; tibial tuberosity; anterior crest; and medial malleolus
- Features of the fibula, including the head, apex, and lateral malleolus
- Names of the tarsal bones from posterior to anterior, and from lateral to medial in the distal row; why they are more fully integrated into the foot than the carpal bones are into the hand
- The system of naming and numbering the 5 metatarsal bones of the foot and 5 sets of phalanges in the digits; why there are 5 digits but only 14 phalanges; the base, body, and head of all 19 metatarsals and phalanges
- Why the elbows and knees flex in opposite directions, and why the largest digit is lateral in the hand but medial in the foot
- Names and locations of the three foot arches

▶ Testing Your Recall

Answers in Appendix A

- Which of these is *not* a paranasal sinus?
 - frontal
 - temporal
 - sphenoidal
 - ethmoidal
 - maxillary
- Which of these is a facial bone?
 - frontal
 - ethmoid
 - occipital
 - temporal
 - lacrimal
- Which of these *cannot* be palpated on a living person?
 - the crista galli
 - the mastoid process
 - the zygomatic arch
 - the superior nuchal line
 - the hyoid bone
- The only vertebrae with transverse foramina are the _____ vertebrae.
 - thoracic
 - coccygeal
 - lumbar
 - cervical
 - sacral
- Thoracic vertebrae do *not* have
 - transverse foramina.
 - costal facets.
 - spinous processes.
 - transverse processes.
 - pedicles.
- The tubercle of a rib articulates with
 - the sternal notch.
 - the margin of the gladiolus.
 - the costal facets of two vertebrae.
 - the body of a vertebra.
 - the transverse process of a vertebra.
- The disc-shaped head of the radius articulates with the _____ of the humerus.
 - radial tuberosity
 - trochlea
 - capitulum
 - olecranon
 - glenoid cavity
- All of the following are carpal bones, *except* the _____, which is a tarsal bone.
 - trapezium
 - triquetrum
 - cuboid
 - pisiform
 - trapezoid
- The bone that supports your body weight when you are sitting down is
 - the acetabulum.
 - the pubis.
 - the ilium.
 - the coccyx.
 - the ischium.

STUDY GUIDE

10. Which of these is the bone of the heel?
 - a. cuboid
 - b. calcaneus
 - c. navicular
 - d. trochlear
 - e. talus
11. Gaps between the cranial bones of an infant are called _____.
12. The external auditory canal is a passage in the _____ bone.
13. Bones of the skull are joined along lines called _____.
14. The _____ bone has greater and lesser wings and protects the pituitary gland.
15. A herniated disc occurs when a ring called the _____ cracks.
16. The transverse ligament of the atlas holds the _____ of the axis in place.
17. The sacroiliac joint is formed where the _____ surface of the sacrum articulates with that of the ilium.
18. The _____ processes of the radius and ulna form bony protuberances on each side of the wrist.
19. Nerves and blood vessels pass through small holes in the skull called _____. The singular form of this word is _____.
20. The _____ arch of the foot extends from the heel to the great toe.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|------------|------------|-------------|
| 1. costo- | 3. dura | 7. pedo- |
| 2. cranio- | 4. glosso- | 8. pterygo- |
| | 5. -icle | 9. supra- |
| | 6. masto- | 10. tarso- |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|--|---|--|
| 1. The internal jugular vein passes out the foramen magnum of the skull and down the neck. | 5. On a living person, it would be possible to palpate the acromion and spine of the scapula but not the muscles of the infraspinous fossa. | 8. The nasal septum is formed by the nasal bone and vomer. |
| 2. The hands have more phalanges than the feet. | 6. If you rest your chin on your hands and your elbows on a table, the coronoid process of the ulna rests on the table. | 9. In strict anatomical terminology, the words <i>arm</i> and <i>leg</i> both refer to regions with only one bone. |
| 3. As an adaptation to pregnancy, the female's pelvis is deeper than the male's. | 7. The lumbar vertebrae do not articulate with any ribs and therefore do not have transverse processes. | 10. Sesamoid bones are found along the sutures between cranial bones in some people. |
| 4. A wristwatch or bracelet normally encircles the area of the carpal (wrist) bones. | | |

► Testing Your Comprehension

- | | | |
|---|---|--|
| 1. Most bones form joints with at least two others. For example, there are 12 joints between vertebra T6 and other, adjacent bones. Identify at least 10 of them. | 3. Between any two of the unfused vertebrae (cervical through lumbar), there is an intervertebral disc—except between C1 and C2. Give some reasons for the unique absence of a disc at that location. | 4. In adolescents, trauma sometimes separates the head of the femur from the neck. Why do you think this is more common in adolescents than in adults? |
| 2. By palpating the hind leg of a cat or dog or by examining a laboratory skeleton, you can see that cats and dogs stand on the heads of their metatarsal bones; the calcaneus does | not touch the ground. How is this similar to the stance of a person wearing high-heeled shoes? How is it different? | 5. Discuss all the ways you can in which the differences between vertebrae C5 and L3 exemplify this book's theme of the unity of form and function. |

- 9.4 Clinical Application: Knee Injuries and Arthroscopic Surgery
- 9.5 Clinical Application: Arthritis and Artificial Joints

BRUSHING UP

- Understanding the anatomy and function of the joints requires familiarity with the names of all the major bones (see table 8.1 and fig. 8.1).
- Understanding joint action also requires knowledge of the surface features of bones, especially at the articular surfaces of the limb bones, described throughout chapter 8 and itemized in general terms in table 8.2.
- Movements of the joints are described with reference to the basic anatomical planes defined in atlas A, figure A.1.

Joints, or articulations, link the bones of the skeletal system into a functional whole—a system that supports the body, permits effective movement, and protects the softer organs. Joints such as the shoulder, elbow, and knee are remarkable specimens of biological design—self-lubricating, almost frictionless, and able to bear heavy loads and withstand compression while executing smooth and precise movements (fig. 9.1). Yet it is equally important that other joints be less movable or even immobile. Such joints are better able to support the body and protect delicate organs. The vertebral column, for example, is only moderately mobile, for it must allow for flexibility of the torso and yet protect the delicate spinal cord and support much of the body's weight. Bones of the cranium must protect the brain and sense organs, but need not allow for movement (except during birth); thus, they are locked together by immobile joints, the sutures studied in chapter 8.

In everyday life, we take the greatest notice of the most freely mobile joints of the limbs, and it is here that people feel most severely compromised by such disabling diseases as arthritis. Much of the work of physical therapists focuses on limb mobility. In this chapter, we will survey all types of joints, from the utterly immobile to the most mobile, but with an emphasis on the latter. This survey of joint anatomy and movements will provide a foundation for the study of muscle actions in chapter 10.

9.1 Joints and Their Classification

Expected Learning Outcomes

When you have completed this section, you should be able to

- explain what joints are, how they are named, and what functions they serve;
- name and describe the four major categories of joints;
- describe the three types of fibrous joints and give an example of each;
- distinguish between the three types of sutures;
- describe the two types of cartilaginous joints and give an example of each; and
- explain, with examples, why some joints change categories as a person ages.

FIGURE 9.1 Joint Flexibility.

Rubberball/Erik Isakson/Getty Images

Any point where two bones meet is called a **joint (articulation)**, whether or not the bones are mobile at that interface. The science of joint structure, function, and dysfunction is called **arthrology**.¹ The study of musculoskeletal movement is **kinesiology**² (kih-NEE-see-OL-oh-jee).

The name of a joint is typically derived from the names of the bones involved. For example, the *atlas–occipital joint* is where the atlas meets the occipital condyles; the *glenohumeral joint* is where the glenoid cavity of the scapula meets the humerus; and the *radioulnar joint* is where the radius meets the ulna.

Joints can be classified according to the manner in which the adjacent bones are bound to each other, with corresponding differences in how freely the bones can move. Authorities differ in their classification schemes, but one common view places the

¹*arthro* = joint; *logy* = study of

²*kinesio* = movement; *logy* = study of

joints in four major categories: *bony*, *fibrous*, *cartilaginous*, and *synovial joints*. This section describes the first three of these and the subclasses of each. The remainder of the chapter will then be concerned primarily with synovial joints.

9.1a Bony Joints

A **bony joint**, or **synostosis**³ (SIN-oss-TOE-sis), is an immobile joint formed when the gap between two bones ossifies and they become, in effect, a single bone. Bony joints can form by ossification of either fibrous or cartilaginous joints. An infant is born with right and left frontal and mandibular bones, for example, but these soon fuse seamlessly into a single frontal bone and mandible. Three childhood bones—the ilium, ischium, and pubis—fuse to form a single hip bone on each side of an adult. The epiphyses and

diaphyses of the long bones are joined by cartilaginous joints in childhood and adolescence, and these become bony joints in early adulthood. In old age, the first rib often fuses with the sternum and the two parietal bones sometimes fuse along the sagittal suture.

9.1b Fibrous Joints

A **fibrous joint** is also called a **synarthrosis**⁴ (SIN-ar-THRO-sis). It is a point at which adjacent bones are bound by collagen fibers that emerge from one bone, cross the space between them, and penetrate into the other (**fig. 9.2**). There are three kinds of fibrous joints: *sutures*, *gomphoses*, and *syndesmoses*. In sutures and gomphoses, the fibers are very short and allow for little or no movement. In syndesmoses, the fibers are longer and the attached bones are more mobile.

³*syn* = together; *ost* = bone; *osis* = condition

⁴*syn* = together; *arthr* = joined; *osis* = condition

FIGURE 9.2 Fibrous Joints. (a) A suture between the parietal bones. (b) A gomphosis between a tooth and the jaw. (c) A syndesmosis between the tibia and fibula.

? If we narrowly define a joint as an attachment of one bone to another, one of these three would not qualify. Which one and why?

Sutures

Sutures are immobile or only slightly mobile fibrous joints that closely bind the bones of the skull to each other; they occur nowhere else. In chapter 8, we didn't take much notice of the differences between one suture and another, but some differences may have caught your attention as you studied the diagrams in that chapter or examined laboratory specimens. Sutures can be classified as *serrate*, *lap*, and *plane* sutures. Readers with some knowledge of woodworking may recognize that the structures and functional properties of these sutures have something in common with basic types of carpentry joints (**fig. 9.3**).

Serrate sutures appear as wavy lines along which the adjoining bones firmly interlock with each other by their serrated margins, like pieces of a jigsaw puzzle. Serrate sutures are analogous to a dovetail wood joint. Examples include the coronal, sagittal, and lambdoid sutures that border the parietal bones.

Lap (squamous) sutures occur where two bones have overlapping beveled edges, like a miter joint in carpentry. On the surface, a lap suture appears as a relatively smooth (nonserrated) line. An example is the squamous suture where the temporal bone meets the sphenoid and parietal bones. The beveled edge of the temporal bone can be seen in figure 8.11b.

Plane (butt) sutures occur where two bones have straight nonoverlapping edges. The two bones merely border on each other,

like two boards glued together in a butt joint. This type of joint is represented by the intermaxillary suture in the roof of the mouth (see fig. 8.5a).

Gomphoses

Even though the teeth are not bones, the attachment of a tooth to its socket is classified as a joint called a **gomphosis** (gom-FOE-sis). The term refers to its similarity to a nail hammered into wood.⁵ The tooth is held firmly in place by a fibrous **periodontal ligament**, which consists of collagen fibers that extend from the bone matrix of the jaw into the dental tissue (see fig. 9.2b). The periodontal ligament allows the tooth to move or give a little under the stress of chewing. Along with associated nerve endings, this slight tooth movement allows us to sense how hard we're biting and to sense a particle of food stuck between the teeth.

Syndesmoses

A **syndesmosis**⁶ (SIN-dez-MO-sis) is a fibrous joint at which two bones are bound by relatively long collagenous fibers. The

⁵*gomph* = nail, bolt; *osis* = condition

⁶*syn* = together; *desm* = band; *osis* = condition

FIGURE 9.3 Sutures. Serrate, lap, and plane sutures compared to some common wood joints.

separation between the bones and length of the fibers give these joints more mobility than a suture or gomphosis has. An especially mobile syndesmosis exists between the shafts of the radius and ulna, which are joined by a broad fibrous *interosseous membrane*. This permits such movements as pronation and supination of the forearm. A less mobile syndesmosis is the one that binds the distal ends of the tibia and fibula together, side by side (see fig. 9.2c).

9.1c Cartilaginous Joints

A **cartilaginous joint** is also called an **amphiarthrosis**⁷ (AM-fee-ar-THRO-sis). In these joints, two bones are linked by cartilage (fig. 9.4). The two types of cartilaginous joints are *synchondroses* and *symphyses*.

Synchondroses

A **synchondrosis**⁸ (SIN-con-DRO-sis) is a joint in which the bones are joined by hyaline cartilage. An example is the temporary joint between the epiphysis and diaphysis of a long bone in a child, formed by the cartilage of the epiphyseal plate. Another is the attachment of the first rib to the sternum by a hyaline costal cartilage

(fig. 9.4a). (The other costal cartilages are joined to the sternum by synovial joints.)

Symphyses

In a **symphysis**⁹ (SIM-fih-sis), two bones are joined by fibrocartilage (fig. 9.4b, c). One example is the pubic symphysis, in which the right and left pubic bones are joined anteriorly by the cartilaginous interpubic disc. Another is the joint between the bodies of two vertebrae, united by an intervertebral disc. The surface of each vertebral body is covered with hyaline cartilage. Between the vertebrae, this cartilage becomes infiltrated with collagen bundles to form fibrocartilage. Each intervertebral disc permits only slight movement between adjacent vertebrae, but the collective effect of all 23 discs gives the spine considerable flexibility.

▶▶▶ APPLY WHAT YOU KNOW

The intervertebral joints are symphyses only in the cervical through the lumbar region. How would you classify the intervertebral joints of the sacrum and coccyx in a middle-aged adult?

⁷*amphi* = on all sides; *arthr* = joined; *osis* = condition

⁸*syn* = together; *chondr* = cartilage; *osis* = condition

⁹*sym* = together; *physis* = growth

FIGURE 9.4 Cartilaginous Joints.

(a) A synchondrosis, represented by the costal cartilage joining rib 1 to the sternum. (b) The pubic symphysis. (c) Intervertebral discs, which join adjacent vertebrae to each other by symphyses.

? What is the difference between the pubic symphysis and the interpubic disc?

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. What is the difference between arthrology and kinesiology?
2. Distinguish between a synostosis, synarthrosis, and amphiarthrosis.
3. Define *suture*, *gomphosis*, and *syndesmosis*, and explain what these three joints have in common.
4. Name the three types of sutures and describe how they differ.
5. Name two synchondroses and two symphyses.
6. Give some examples of joints that become synostoses with age.

9.2 Synovial Joints

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. identify the anatomical components of a typical synovial joint;
- b. classify any given joint action as a first-, second-, or third-class lever;
- c. explain how mechanical advantage relates to the power and speed of joint movement;
- d. discuss the factors that determine a joint's range of motion;
- e. describe the primary axes of rotation that a bone can have and relate this to a joint's degrees of freedom;
- f. name and describe six classes of synovial joints; and
- g. use the correct standard terminology for various joint movements.

The most familiar type of joint is the **synovial joint** (sih-NO-vee-ul), also called a **diarthrosis**¹⁰ (DY-ar-THRO-sis). Ask most people to point out any joint in the body, and they're likely to point to a synovial joint such as an elbow, knee, or knuckle. Many synovial joints, like these examples, are freely mobile. Others, such as the joints between the wrist and ankle bones and between the articular processes of the vertebrae, have more limited mobility.

Synovial joints are the most structurally complex type of joint and are the type most likely to develop uncomfortable and crippling dysfunctions. They're the most important joints for such professionals as physical and occupational therapists, athletic coaches, nurses, and fitness trainers to understand well. Their mobility makes the synovial joints especially important to the quality of life. Reflect, for example, on the performance extremes of a young athlete, the decline in flexibility that comes with age, and the crippling effect of rheumatoid arthritis. The rest of this chapter is concerned with synovial joints.

9.2a General Anatomy

In synovial joints, the facing surfaces of the two bones are covered with **articular cartilage**, a layer of hyaline cartilage up to 2 or 3 mm thick. These surfaces are separated by a narrow space, the **joint (articular) cavity**, containing a slippery lubricant called **synovial fluid** (fig. 9.5). This fluid, for which the joint is named, is rich in albumin and hyaluronic acid, which give it a viscous, slippery texture similar to raw egg white.¹¹ It nourishes the articular cartilages, removes their wastes, and makes movements at synovial joints almost friction-free. A connective tissue **joint (articular) capsule** encloses the cavity and retains the fluid. It has an outer **fibrous capsule** continuous with the periosteum of the adjoining bones, and an inner, cellular **synovial membrane**. The synovial membrane is composed mainly of fibroblast-like cells that secrete the fluid, and is populated by macrophages that remove debris from the joint cavity. Joint capsules and ligaments are well supplied with *lamellar corpuscles* (see chapter 16) and other sensory nerve endings that enable the brain to monitor limb positions and joint movements.

In a few synovial joints, fibrocartilage grows inward from the joint capsule and forms a pad between the articulating bones. In the jaw (temporomandibular) joint, at both ends of the clavicle (sternoclavicular and acromioclavicular joints), and between the ulna and carpal bones, the pad crosses the entire joint capsule and

¹¹ *ovi* = egg

FIGURE 9.5 Structure of a Simple Synovial Joint.

? Why is a meniscus unnecessary in an interphalangeal joint?

¹⁰ *dia* = separate, apart; *arthr* = joint; *osis* = condition

is called an **articular disc** (see fig. 9.23c). In the knee, two cartilages extend inward from the left and right but don't entirely cross the joint (see fig. 9.28d). Each is called a **meniscus**¹² because of its crescent-moon shape. These cartilages absorb shock and pressure, guide the bones across each other, improve the fit between the bones, and stabilize the joint, reducing the chance of dislocation.

Accessory structures associated with a synovial joint include tendons, ligaments, and bursae. A **tendon** is a strip or sheet of tough collagenous connective tissue that attaches a muscle to a bone. Tendons are often the most important structures in stabilizing a joint. A **ligament** is a similar tissue that attaches one bone to another. Several ligaments are named and illustrated in our discussion of individual joints later in this chapter, and tendons are more fully considered in chapter 10 along with the gross anatomy of muscles.

A **bursa**¹³ is a fibrous sac of synovial fluid located between adjacent muscles, where a tendon passes over a bone, or between bone and skin (see fig. 9.24). Bursae cushion muscles, help tendons slide more easily over the joints, and sometimes enhance the mechanical effect of a muscle by modifying the direction in which its tendon pulls. **Tendon (synovial) sheaths** are elongated cylindrical bursae wrapped around a tendon, seen especially in the hand and foot (**fig. 9.6**). They enable tendons to move back and forth more freely in such tight spaces as the wrist and ankle.

¹²*men* = moon, crescent; *isc* = little

¹³*bursa* = purse

DEEPER INSIGHT 9.1

CLINICAL APPLICATION

Exercise and Articular Cartilage

When synovial fluid is warmed by exercise, it becomes thinner (less viscous), like warm oil, and more easily absorbed by the articular cartilage. The cartilage then swells and provides a more effective cushion against compression. For this reason, a warm-up period before vigorous exercise helps protect the articular cartilage from undue wear and tear.

Because cartilage is nonvascular, repetitive compression during exercise is important to its nutrition and waste removal. Each time a cartilage is compressed, fluid and metabolic wastes are squeezed out of it. When weight is taken off the joint, the cartilage absorbs synovial fluid like an expanding sponge, and the fluid carries oxygen and nutrients to the chondrocytes. Without exercise, articular cartilages deteriorate more rapidly from inadequate nutrition, oxygenation, and waste removal.

Weight-bearing exercise builds bone mass and strengthens the muscles that stabilize many of the joints, thus reducing the risk of joint dislocations. Excessive joint stress, however, can hasten the progression of osteoarthritis by damaging the articular cartilage (see Deeper Insight 9.5). Swimming and bicycling are good ways of exercising the joints with minimal damage.

FIGURE 9.6 Tendon Sheaths and Other Bursae in the Hand and Wrist.

9.2b Joints and Lever Systems

Many bones, especially the long bones, act as levers to enhance the speed or power of limb movements. A lever is any elongated, rigid object that rotates around a fixed point called the **fulcrum** (fig. 9.7). Rotation occurs when an effort applied to one point on the lever overcomes a resistance (load) at some other point. The portion of a lever from the fulcrum to the point of effort is called the **effort arm**, and the part from the fulcrum to the point of resistance is called the **resistance arm**. In skeletal anatomy, the fulcrum is a joint; the effort is applied by a muscle; and the resistance can be an object against which the body is working (as in weight lifting), the weight of the limb itself, or the tension in an opposing muscle.

Levers, Speed, and Force

The function of a lever is to produce a gain in the speed, distance, or force of a motion—either to exert more force against a resisting object than the force applied to the lever (for example, in moving a heavy object with a crowbar), or to move the resisting object farther or faster than the effort arm is moved (as in rowing a boat, where the blade of the oar moves much farther and faster than the handle). A single lever cannot confer both advantages. There is a trade-off between force on one hand and speed or distance on the other—as one increases, the other decreases.

The **mechanical advantage (MA)** of a lever is the ratio of its output force to its input force. If L_E is the length of the effort arm and L_R is the length of the resistance arm,

$$MA = L_E / L_R.$$

If MA is greater than 1.0, the lever produces more force, but less speed or distance, than the force exerted on it. If MA is less than 1.0, the lever produces more speed or distance, but less force, than the input (fig. 9.8a, b).

Consider, for example, the action of the brachialis muscle on the ulna when it flexes the elbow (fig. 9.8c). We will regard the ulna as the lever and the hand, along with whatever is in it, as the

FIGURE 9.8 Mechanical Advantage (MA). (a) $MA > 1$ in a first-class lever with $L_E > L_R$. (b) $MA < 1$ in a first-class lever with $L_E < L_R$. (c) $MA < 1$ in the forearm; when acted upon by the brachialis muscle, this is a third-class lever.

load or resistance being moved. The fulcrum of this lever is the humeroulnar joint. The brachialis tendon attaches to the ulna only slightly distal to the joint, so the effort arm is very short. The resistance arm extends from the joint to the load on the muscle (such as the weight in the hand), so L_R is much greater than L_E . Considering a typical ulna measuring 5 cm from the joint to the brachialis tendon and 33 cm from the joint to the load, the mechanical advantage would be $MA = 5/33 = 0.15$. As expected, with this $MA < 1$, the hand travels with more speed and distance than the point of brachialis attachment.

FIGURE 9.7 The Basic Components of a Lever. This example is a first-class lever.

? What would be the mechanical advantage of the lever shown here? Where would you put the fulcrum to increase the mechanical advantage without changing the lever class?

In chapter 10, you will often find that two or more muscles act on the same joint, seemingly producing the same effect. This may seem redundant, but it makes sense if the tendinous attachments of the muscles are at different points on a bone and produce different mechanical advantages. A sprinter taking off from the starting line, for example, uses “low-gear” (high-*MA*) muscles that don’t generate much speed, but have the power to overcome the inertia of the body. The runner then “shifts into high gear” by using muscles with different attachments that confer a lower mechanical advantage but produce more speed at the feet. This is analogous to the way an automobile transmission uses one gear to get a car moving and other gears to cruise at higher speeds.

Types of Levers

There are three classes of levers that differ with respect to which component is in the middle—the fulcrum (F), effort (E), or resistance (R) (**fig. 9.9**).

1. A **first-class lever** is one with the fulcrum in the middle (EFR), such as a seesaw. An anatomical example is the atlanto–occipital joint of the neck, where the muscles of the back of the neck pull down on the occipital bone of the skull and oppose the tendency of the head to tip forward. Loss of muscle tone here can be embarrassing if you nod off in class. Rocking of the foot on the tibia as the toes are raised and lowered also exemplifies a first-class lever. (It is often misinterpreted as a second-class lever because of a superficial resemblance between standing on tiptoes and the wheelbarrow example that follows.)
2. A **second-class lever** has the resistance in the middle (FRE). Lifting the handles of a wheelbarrow, for example, causes it to pivot on the axle of the wheel at the opposite end and lift a load in the middle. If you sit in a chair and raise one thigh, like bouncing a child on your knee, the femur pivots on the hip joint (the fulcrum), the quadriceps femoris muscle of the anterior thigh elevates the tibia like the wheelbarrow handles, and the resistance is the weight of the child or the thigh itself.
3. In a **third-class lever**, the effort is applied between the fulcrum and resistance (REF). For example, in paddling a canoe, the relatively stationary grip at the upper end of the paddle is the fulcrum, the effort is applied to the middle of the shaft, and the resistance is produced by the water against the blade. Most musculoskeletal levers are third class. The forearm acts as a third-class lever when you flex your elbow. The fulcrum is the joint between the ulna and humerus, the effort is applied partly by the biceps brachii muscle, and the resistance can be any weight in the hand or the weight of the forearm itself.

The classification of a lever changes as it performs different actions. We use the forearm as a third-class lever when we flex the elbow, as in weight lifting, but we use it as a first-class lever when we extend it, as in hammering nails. The mandible is a second-class lever when we open the mouth and a third-class lever when we close it to bite off a piece of food.

Range of Motion

One aspect of joint performance and physical assessment of a patient is a joint’s flexibility, or **range of motion (ROM)**—the degrees through which a joint can move. The knee, for example, can flex through an arc of 130° to 140°, the metacarpophalangeal joint of the index finger about 90°, and the ankle about 74°. *ROM* obviously affects a person’s functional independence and quality of life. It is also an important consideration in training for athletics or dance, in clinical diagnosis, and in monitoring the progress of rehabilitation. The *ROM* of a joint is normally determined by the following factors:

- **Structure of the articular surfaces of the bones.** In many cases, joint movement is limited by the shapes of the bone surfaces. For example, you cannot straighten your elbow beyond 180° or so because, as it straightens, the olecranon of the ulna swings into the olecranon fossa of the humerus and the fossa prevents it from moving any farther.
- **Strength and tautness of ligaments and joint capsules.** Some bone surfaces impose little if any limitation on joint movement. The articulations of the phalanges are an example; as one can see by examining a dry skeleton, an interphalangeal joint can bend through a broad arc. In the living body, however, these bones are joined by ligaments that limit their movement. As you flex one of your knuckles, ligaments on the anterior (palmar) side of the joint go slack, but ligaments on the posterior (dorsal) side tighten and prevent the joint from flexing beyond 90° or so. The knee is another case in point. In kicking a football, the knee rapidly extends to about 180°, but it can go no farther. Its motion is limited in part by a *cruciate ligament* and other knee ligaments described later. Gymnasts, dancers, and acrobats increase the *ROM* of their synovial joints by gradually stretching their ligaments during training. “Double-jointed” people have unusually large *ROMs* at some joints, not because the joint is actually double or fundamentally different from normal in its anatomy, but because the ligaments are unusually long or slack.
- **Action of the muscles and tendons.** Extension of the knee is also limited by the *hamstring muscles* on the posterior side of the thigh. In many other joints, too, pairs of muscles oppose each other and moderate the speed and range of joint motion. Even a resting muscle maintains a state of tension called *muscle tone*, which serves in many cases to stabilize a joint. One of the major factors preventing dislocation of the shoulder joint, for example, is tension in the *biceps brachii* muscle, whose tendons cross the joint, insert on the scapula, and hold the head of the humerus against the glenoid cavity. The nervous system continually monitors and adjusts joint angles and muscle tone to maintain joint stability and limit unwanted movements.

Axes of Rotation

In solid geometry, we recognize three mutually perpendicular axes, *x*, *y*, and *z*. In anatomy, these correspond to the transverse, frontal, and sagittal planes of the body. Just as we can describe any point

FIGURE 9.9 The Three Classes of Levers. Left: The lever classes defined by the relative positions of the resistance (load), fulcrum, and effort. Center: Mechanical examples. Right: Anatomical examples. (a) Muscles of the back of the neck pull down on the occipital bone to oppose the tendency of the head to drop forward. The fulcrum is the occipital condyles. (b) The quadriceps muscle of the anterior thigh elevates the knee. The fulcrum is the hip joint. (c) In flexing the elbow, the biceps brachii muscle exerts an effort on the radius. Resistance is provided by the weight of the forearm or anything held in the hand. The fulcrum is the elbow joint.

in space by its x , y , and z coordinates, we can describe any joint movement by reference to the transverse, frontal, or sagittal anatomical planes.

A moving bone has a relatively stationary **axis of rotation** that passes through the bone in a direction perpendicular to the plane of movement. Think of a door for comparison; it moves horizontally as it opens and closes, and it rotates on hinges that are oriented on the vertical axis. Now consider the shoulder joint (**fig. 9.10**), where

the convex head of the humerus inserts into the concave glenoid cavity of the scapula. If you raise your arm to one side of your body, the head of the humerus rotates on an axis that passes from anterior to posterior; the arm rises in the frontal plane whereas its axis of rotation is in the sagittal plane. If you lift your arm to point at something straight in front of you, it moves through the sagittal plane whereas its axis of rotation is on the frontal plane, passing through the shoulder from lateral to medial. And if you swing your

FIGURE 9.10 Axes of Joint Rotation. (a) Abduction of the arm in the frontal plane. (b) Flexion of the arm in the sagittal plane. (c) Internal rotation of the arm. All three axes are represented in movements of the multiaxial ball-and-socket joint of the shoulder.

arm in a horizontal arc, for example to grasp the opposite shoulder, the humeral head rotates in the transverse plane and its axis of rotation passes vertically through the joint.

Because the arm can move in all three anatomical planes, the shoulder joint is said to have three **degrees of freedom**, or to be a **multiaxial** joint. Other joints move through only one or two planes; they have one or two degrees of freedom and are called **monaxial** and **biaxial** joints, respectively. Degrees of freedom are a factor used in classifying the synovial joints.

Classes of Synovial Joints

There are six fundamental types of synovial joints, distinguished by the shapes of their articular surfaces and their degrees of freedom. We'll begin by looking at these six types in simple terms, but then see that this is an imperfect classification for reasons discussed at the end. All six types can be found in the upper limb (**fig. 9.11**). They are listed here in descending order of mobility: one multiaxial type (ball-and-socket), three biaxial types (condylar, saddle, and plane), and two monaxial types (hinge and pivot).

1. **Ball-and-socket joints.** These are the shoulder and hip joints—the only multiaxial joints in the body. In both cases, one bone (the humerus or femur) has a smooth hemispherical head that fits into a cuplike socket on the other (the glenoid cavity of the scapula or the acetabulum of the hip bone).
2. **Condylar (ellipsoid) joints.** These joints exhibit an oval convex surface on one bone that fits into a complementary-shaped depression on the other. The radiocarpal joint of the wrist and metacarpophalangeal (MET-uh-CAR-po-fah-LAN-jee-ul) joints at the bases of the fingers are examples. They are biaxial

joints, capable of movement in two planes. To demonstrate this, hold your hand with the palm facing you. Make a fist, and these joints flex in the sagittal plane. Fan your fingers apart, and they move in the frontal plane.

3. **Saddle joints.** Here, both bones have a saddle-shaped surface—concave in one direction (like the front-to-rear curvature of a horse's saddle) and convex in the other (like the left-to-right curvature of a saddle). The clearest example of this is the trapeziometacarpal joint between the trapezium of the wrist and metacarpal I at the base of the thumb. Saddle joints are biaxial. The thumb, for example, moves in a frontal plane when you spread the fingers apart, and in a sagittal plane when you move it as if to grasp a tool such as a hammer. This range of motion gives us and other primates that invaluable anatomical hallmark, the opposable thumb. Another saddle joint is the sternoclavicular joint, where the clavicle articulates with the sternum. The clavicle moves vertically in the frontal plane at this joint when you lift a suitcase, and moves horizontally in the transverse plane when you reach forward to push open a door.
4. **Plane (gliding) joints.** Here the bone surfaces are flat or only slightly concave and convex. The adjacent bones slide over each other and have relatively limited movement. Plane joints are found between the carpal bones of the wrist, the tarsal bones of the ankle, and the articular processes of the vertebrae. Their movements, although slight, are complex. They are usually biaxial. For example, when the head is tilted forward and back, the articular facets of the vertebrae slide anteriorly and posteriorly; when the head is tilted from side to side, the facets slide laterally. Although any one joint moves only slightly, the combined action of the many joints in the wrist, ankle, and spine allows for a significant amount of overall movement.
5. **Hinge joints.** These are essentially monaxial joints, moving freely in one plane with very little movement in any other, like a door hinge. Some examples are the elbow, knee, and interphalangeal (finger and toe) joints. In these cases, one bone has a convex (but not hemispherical) surface, such as the trochlea of the humerus and the condyles of the femur. This fits into a concave depression on the other bone, such as the trochlear notch of the ulna and the condyles of the tibia.
6. **Pivot joints.** These are monaxial joints in which a bone spins on its longitudinal axis like a bicycle wheel spinning on its axle. There are two principal examples: the atlantoaxial joint between the first two vertebrae, and the radioulnar joint at the elbow. At the atlantoaxial joint, the dens of the axis projects into the vertebral foramen of the atlas and is held against the anterior arch of the atlas by the transverse ligament (see **fig. 8.26c**). As the head rotates left and right, the skull and atlas pivot around the dens. At the radioulnar joint, the annular ligament of the ulna wraps around the neck of the radius. During pronation and supination of the forearm, the disclike radial head pivots like a wheel turning on its axle. The edge of the wheel spins against the radial notch of the ulna like a car tire spinning in snow.

FIGURE 9.11 The Six Types of Synovial Joints. All six have representatives in the forelimb. Mechanical models show the types of motion possible at each joint.

Some joints can't be easily classified into any one of these six categories. The jaw joint, for example, has some aspects of condylar, hinge, and plane joints. It clearly has an elongated condyle where it meets the temporal bone of the cranium, but it moves in a hingelike fashion when the mandible moves up and down in speaking, biting, and chewing; it glides slightly forward when the jaw juts forward to take a bite; and it glides from side to side to grind food between the molars. To observe the importance of the forward glide, try to open

your mouth while pushing the jaw posteriorly with the heel of your hand; it is difficult to open the mouth more than 1 or 2 cm when there is resistance to protraction of the mandible.

The knee is a classical hinge joint, but has an element of the pivot type; when we lock our knees to stand more effortlessly, the femur pivots slightly on the tibia. The humeroradial joint acts as a hinge joint when the elbow flexes and a pivot joint when the forearm pronates.

9.2c Movements of Synovial Joints

Kinesiology, physical therapy, and other medical and scientific fields have a specific vocabulary for the movements of synovial joints. The following terms form a basis for describing the muscle actions in chapter 10 and may also be indispensable to your advanced coursework or intended career. This section introduces the terms for joint movements, many of which are presented in pairs or groups with opposite or contrasting meanings. This section relies on familiarity with the three cardinal anatomical planes and the directional terms in atlas A, table A.1. All directional terms used here refer to a person in standard anatomical position. When one is standing in anatomical position, each joint is said to be in its **zero position**. Joint movements can be described as deviating from the zero position or returning to it.

Flexion and Extension

Flexion (fig. 9.12) is a movement that decreases a joint angle, usually in the sagittal plane. This is particularly common at hinge joints—for example, bending the elbow so that the arm and forearm go from a 180° angle to 90° or less. It occurs in other types of joints as well. For example, if you hold out your hands with the palms up, flexion of the wrist tips your palms toward you. The meaning of *flexion* is perhaps least obvious in the ball-and-socket joints of the shoulder and hip. At the shoulder, it means to raise your arm as if pointing at something directly in front of you or to continue in that arc and point toward the sky. At the hip, it means to raise the thigh, for example to place your foot on the next higher step when ascending a flight of stairs.

a–d: Timothy L. Vacula/Ken Saladin

Extension (fig. 9.12) is a movement that straightens a joint and generally returns a body part to the zero position—for example, straightening the elbow, wrist, or knee, or returning the arm or thigh back to zero position. In stair climbing, both the hip and knee extend when lifting the body to the next higher step.

Further extension of a joint beyond the zero position is called **hyperextension**.¹⁴ For example, if you hold your hand in front of you with the palm down, then raise the back of your hand as if you were admiring a new ring, you hyperextend the wrist. Hyperextension of the upper or lower limb means to move the limb to a position behind the frontal plane of the trunk, as if reaching around with your arm to scratch your back. Each backswing of the lower limb when you walk hyperextends the hip.

Flexion and extension occur at nearly all diarthroses, but hyperextension is limited to only a few. At most diarthroses, ligaments or bone structures prevent hyperextension.

¹⁴*hyper* = excessive, beyond normal

Abduction and Adduction

Abduction¹⁵ (ab-DUC-shun) (fig. 9.13a) is the movement of a body part in the frontal plane away from the midline of the body—for example, moving the feet apart to stand spread-legged, or raising an arm to one side of the body. **Adduction**¹⁶ (fig. 9.13b) is movement in the frontal plane back toward the midline. Some joints can be **hyperadducted**, as when you stand with your ankles crossed, cross your fingers, or hyperadduct the shoulder to stand with your elbows straight and your hands clasped below your waist. You **hyperabduct** the arm if you raise it high enough to cross slightly over the front or back of your head.

Elevation and Depression

Elevation (fig. 9.14a) is a movement that raises a body part vertically in the frontal plane. **Depression** (fig. 9.14b) lowers a

a–b: Timothy L. Vacula/Ken Saladin

body part in the same plane. For example, to lift a suitcase from the floor, you elevate your scapula; in setting it down again, you depress the scapula. These are also important jaw movements in biting.

Protraction and Retraction

Protraction¹⁷ (fig. 9.15a) is the anterior movement of a body part in the transverse (horizontal) plane, and **retraction**¹⁸ (fig. 9.15b) is posterior movement. Your shoulder protracts, for example, when you reach in front of you to push a door open. It retracts when you return it to the resting (zero) position or pull the shoulders back to stand at military attention. Such exercises as rowing a boat, bench presses, and push-ups involve repeated protraction and retraction of the shoulders.

Circumduction

In **circumduction**¹⁹ (fig. 9.16), one end of an appendage remains fairly stationary while the other end makes a circular motion. If an artist standing at an easel reaches forward and draws a circle on a canvas, she circumducts the upper limb; the shoulder remains stationary while the hand moves in a circle. A baseball player winding up for the pitch circumducts the upper limb in a more extreme “windmill” fashion. One can also circumduct an individual finger, the hand, the thigh, the foot, the trunk, and the head.

FIGURE 9.16
Circumduction.

Timothy L. Vacula/Ken Saladin

▶▶▶ APPLY WHAT YOU KNOW

Choose any example of circumduction and explain why this motion is actually a sequence of flexion, abduction, extension, and adduction.

Rotation

Rotation (fig. 9.17) is a movement in which a bone spins on its longitudinal axis like a bicycle wheel. For example, if you stand with bent elbow and move your forearm to grasp your opposite arm, your humerus spins in a motion called **medial (internal) rotation**. If you make the opposite action, so the forearm points away from your trunk, your humerus undergoes **lateral (external) rotation**.

(a) Medial (internal) rotation

(b) Lateral (external) rotation

FIGURE 9.17 Medial (Internal) and Lateral (External) Rotation. (a) Medial (internal) rotation of the humerus and femur. (b) Lateral (external) rotation of both.

¹⁷*pro* = forward; *trac* = to pull or draw

¹⁸*re* = back; *trac* = to pull or draw

¹⁹*circum* = around; *duc* = to carry, lead

rotation. Good examples of lateral and medial rotation of the humerus are its movements in the forehand and backhand strokes of tennis. The femur can also rotate. If you stand and turn your right foot so your toes point toward your left foot, then turn it so your toes point away from the left foot, your femur undergoes medial and lateral rotation, respectively. Other examples are given in the coming discussions of forearm and head movements.

Supination and Pronation

Supination and pronation are known primarily as forearm movements, but see also the later discussion of foot movements. **Supination**²⁰ (SOO-pih-NAY-shun) (fig. 9.18a) of the forearm is a movement that turns the palm to face anteriorly or upward; in anatomical position, the forearm is supinated and the radius is parallel to the ulna. **Pronation**²¹ (fig. 9.18b) is the opposite movement, causing the palm to face posteriorly or downward, and the radius to cross the ulna like an X. During these movements, the concave end of the disc-shaped head of the radius spins on the capitulum of the humerus, and the edge of the disc spins in the radial notch of the ulna. The ulna remains relatively stationary.

As an aid to remembering these terms, think of it this way: You are *prone* to stand in the most comfortable position, which is with the forearm *pronated*. But if you were holding a bowl of *soup* in your palm, you would need to *supinate* the forearm to keep from spilling it.

Chapter 10 describes the muscles that perform these actions (see table 10.10). Of these, the *supinator* is the most powerful. Supination is the type of movement you would usually make with your right hand to turn a doorknob clockwise or to drive a screw into a piece of wood. The threads of screws and bolts are designed with the relative strength of the supinator in mind, so the greatest power can be applied when driving them with a screwdriver in the right hand.

We will now consider a few body regions that combine the foregoing motions, or that have unique movements and terminology.

Special Movements of the Head and Trunk

Flexion of the spine produces forward-bending movements, as in tilting the head forward or bending at the waist in a toe-touching exercise (fig. 9.19a). **Extension** of the vertebral column straightens the trunk or the neck, as in standing up or returning the head to a forward-looking zero position. **Hyperextension** is employed in looking up toward the sky or bending over backward (fig. 9.19b). **Lateral flexion** is tilting the head or trunk to the right or left of the midline (fig. 9.19c).

Twisting at the waist or turning of the head is called **right rotation** or **left rotation** when the chest or the face turns to the right or left of the forward-facing zero position (fig. 9.19d, e). Powerful right and left rotation at the waist is important in baseball pitching, golf, discus throwing, and other sports. Rotation at the waist is not

a true joint movement, however, as it doesn't change the relationship of any bones to each other at any synovial joints.

(a) Supination

(b) Pronation

FIGURE 9.18 Supination and Pronation of the Forearm.

Special Movements of the Mandible

Movements of the mandible are concerned especially with biting and chewing. Imagine taking a bite of raw carrot. Most people have some degree of overbite; at rest, the upper incisors (front teeth) overhang the lower ones. For effective biting, however, the chisel-like edges of the incisors must meet. In preparation to bite, we therefore *protract* the mandible to bring the lower incisors forward. After the bite is taken, we *retract* it (**fig. 9.20a, b**). To actually take the bite, we must *depress* the mandible to open the mouth, then *elevate* it so the incisors cut off the piece of food.

Next, to chew the food, we don't simply raise and lower the mandible as if hammering away at the food between the teeth; rather, we exercise a grinding action that shreds the food between the broad, bumpy surfaces of the premolars and molars. This entails a side-to-side movement of the mandible called **lateral excursion** (movement to the left or right of the zero position) and **medial excursion** (movement back to the median, zero position) (**fig. 9.20c, d**).

Special Movements of the Hand and Digits

The hand moves anteriorly and posteriorly by flexion and extension of the wrist. It can also move in the frontal plane. **Ulnar flexion**

tilts the hand toward the little finger, and **radial flexion** tilts it toward the thumb (**fig. 9.21a, b**). We often use such motions when waving hello to someone with a side-to-side wave of the hand, or when washing windows, polishing furniture, or keyboarding.

Movements of the digits are more varied, especially those of the thumb. *Flexion* of the fingers is curling them; *extension* is straightening them. Most people cannot hyperextend their fingers. Spreading the fingers apart is *abduction* (**fig. 9.21c**), and bringing them together again so they touch along their edges is *adduction* (as in **fig. 9.21a, b**).

The thumb is different, however, because in embryonic development it rotates nearly 90° from the rest of the hand. If you hold your hand in a completely relaxed position (but not resting on a table), you will probably see that the plane that contains your thumb and index finger is about 90° to the plane that contains the index through little fingers. Much of the terminology of thumb movement therefore differs from that of the other four fingers. *Flexion* of the thumb is bending the joints so the tip of the thumb is directed toward the palm, and *extension* is straightening it. If you now place the palm of your hand on a tabletop with all five digits parallel and touching, the thumb is extended. Keeping your hand there, if you move your thumb away from the index finger so they

FIGURE 9.20 Movements of the Mandible. (a) Protraction and (b) retraction. (c) Lateral and (d) medial excursion, as in chewing food.

a–d: Timothy L. Vacula/Ken Saladin

form a 90° angle (but both are on the plane of the table), the thumb movement is called **radial abduction** (as in fig. 9.21c). Another movement, **palmar abduction**, moves the thumb away from the plane of the hand so it points anteriorly, as you would do if you were about to wrap your hand around a tool handle (fig. 9.21d). From either position—radial or palmar abduction—**adduction** of the thumb means to bring it back to zero position, touching the base of the index finger.

Two terms are unique to the thumb: **Opposition**²² means to move the thumb to approach or touch the tip of any of the other four fingers (fig. 9.21e). **Reposition**²³ is the return to zero position.

Special Movements of the Foot

A few additional movement terms are unique to the foot. **Dorsiflexion** is a movement in which the toes are elevated, as you might do to trim your toenails (fig. 9.22a). In each step you take, the foot dorsiflexes as it comes forward. This prevents you from scraping your toes on the ground and results in the characteristic *heel strike* of human locomotion when the foot touches down in front of you. **Plantar flexion** is movement of the foot so the toes point downward, as in pressing the gas pedal of a car or standing on tiptoes. This motion also produces the *toe-off* in each step you take, as the heel of the foot behind you lifts off the ground. Plantar flexion can be a very powerful motion, epitomized by high jumpers and the jump shots of basketball players.

FIGURE 9.22 Movements of the Foot. (a) Plantar flexion and dorsiflexion of the ankle. (b) Inversion of the feet. (c) Eversion of the feet.

a–c: Timothy L. Vacula/Ken Saladin

Inversion²⁴ is a foot movement that tips the soles medially, somewhat facing each other, and **eversion**²⁵ is a movement that tips the soles laterally, away from each other (fig. 9.22b, c). These movements are important in walking on uneven surfaces such as a rocky trail. They are common in fast sports such as tennis and football, and sometimes cause ankle sprains. These terms also refer to congenital deformities of the feet, which are often corrected by orthopedic shoes or braces.

Pronation and *supination*, referring mainly to forearm movements, also apply to the feet but refer here to a more complex combination of movements. Pronation of the foot is a combination of dorsiflexion, eversion, and abduction—that is, the toes are elevated and turned away from the other foot and the sole is tilted away from the other foot. Supination of the foot is a combination of plantar flexion, inversion, and adduction—the toes are lowered and turned toward the other foot and the sole is tilted toward it. These may seem a little difficult to visualize and consciously perform, but they are common motions in walking, running, ballet, and crossing uneven surfaces.

You can perhaps understand why these terms apply to the feet if you place the palms of your hands on a table and pretend they are your soles. Tilt your hands so the inner edge (thumb side) of each is raised from the table. This is like raising the medial edge of your foot from the ground, and as you can see, it involves a slight supination of your forearms. Resting your hands palms down on a table, your forearms are already pronated; but if you raise the outer edges of your hands (the little finger side), like pronating the feet, you will see that it involves a continuation of the pronation movement of the forearm.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- Describe the roles of articular cartilage and synovial fluid in joint mobility.

- Give an anatomical example of each class of levers and explain why each example belongs in that class.
- Give an example of each of the six classes of synovial joints and state how many axes of rotation each example has.
- Suppose you reach overhead and screw a lightbulb into a ceiling fixture. Name each joint that would be involved and the joint actions that would occur.
- Where are the effort, fulcrum, and resistance in the act of dorsiflexion? What class of lever does the foot act as during dorsiflexion? Would you expect it to have a mechanical advantage greater or less than 1.0? Why?

9.3 Anatomy of Selected Diarthroses

Expected Learning Outcomes

When you have completed this section, you should be able to

- identify the major anatomical features of the jaw, shoulder, elbow, hip, knee, and ankle joints; and
- explain how the anatomical differences between these joints are related to differences in function.

We now examine the gross anatomy of certain diarthroses. It is beyond the scope of this book to discuss all of them, but the ones selected here most often require medical attention and many of them have a strong bearing on athletic performance and everyday mobility.

9.3a The Jaw Joint

The **temporomandibular (jaw) joint (TMJ)** is the articulation of the condyle of the mandible with the mandibular fossa of the temporal bone (fig. 9.23). You can feel its action by pressing your fingertips against the jaw immediately anterior to the ear while opening and closing your mouth.

The synovial cavity of the TMJ is divided into superior and inferior chambers by an articular disc, which permits lateral and

²⁴*in* = inward; *version* = turning

²⁵*e* = outward; *version* = turning

FIGURE 9.23 The Temporomandibular (Jaw) Joint (TMJ). (a) Lateral view. (b) Medial view of bisected skull. (c) Sagittal section of joint. **APR**

medial excursion of the mandible. Two ligaments support the joint. The **lateral ligament** prevents posterior displacement of the mandible. If the jaw receives a hard blow, this ligament normally prevents the condylar process from being driven upward and fracturing the base of the skull. The **sphenomandibular ligament** on

the medial side of the joint extends from the sphenoid bone to the ramus of the mandible. A *stylomandibular ligament* extends from the styloid process to the angle of the mandible but isn't part of the TMJ proper.

A deep yawn or other strenuous depression of the mandible can dislocate the TMJ by making the condyle pop out of the fossa and slip forward. The joint is relocated by pressing down on the molars while pushing the jaw posteriorly.

DEEPER INSIGHT 9.2

CLINICAL APPLICATION

TMJ Dysfunction

Temporomandibular joint dysfunction (TMD) afflicts 20% to 30% of the adult population worldwide, and ranks second only to toothache among the most common causes of orofacial pain. It seems to be a cluster of disorders with symptoms that include clicking, popping, or grating noises; restricted jaw movements that may cause problems eating or speaking; and aching pain in the TMJ and associated chewing muscles that intensifies in chewing and yawning. The causes of TMD are so poorly understood that there is no agreement on the best treatment and there are, indeed, more than a dozen different names for it. Pain medication (analgesics) can be helpful. Since TMD is often associated with anxiety, depression, or stress, some patients and physicians report success with behavioral therapies as diverse as meditation, biofeedback, and yoga.

9.3b The Shoulder Joint

The **glenohumeral (humeroscapular) joint**, or shoulder joint, is where the hemispherical head of the humerus articulates with the glenoid cavity of the scapula (**fig. 9.24**). Together, the shoulder and elbow joints serve to position the hand for the performance of a task; without a hand, shoulder and elbow movements are almost useless. The relatively loose shoulder joint capsule and shallow glenoid cavity sacrifice joint stability for freedom of movement (see Deeper Insight 9.3). The cavity, however, has a ring of fibrocartilage called the **glenoid labrum**²⁶ around its margin, making it somewhat deeper than it looks on a dried skeleton.

²⁶ *glen* = socket; *oid* = resembling; *labrum* = lip

FIGURE 9.24 The Glenohumeral (Shoulder) Joint. (a) Anterior view of dissected cadaver shoulder. (b) Anterior view of shoulder ligaments and bursae. (c) Frontal section, showing joint cavity. (d) Lateral view of the shoulder socket (glenoid cavity of the scapula) with the humerus removed. **APR**

DEEPER INSIGHT 9.3

CLINICAL APPLICATION

Shoulder Dislocation

The anatomy and mobility of the shoulder joint make it especially susceptible to dislocation. Over 95% of cases are classified as *anterior dislocation* (displacement of the humeral head in the anterior direction). Such dislocations are usually caused when the arm is abducted and receives a blow from above—for example, from heavy objects falling from a shelf. A complex of nerves and blood vessels traverses the axillary region, and shoulder dislocation can easily damage the axillary nerve or artery

(see figs. 13.17 and 20.39). Left untreated, this can lead to muscle atrophy, weakness, or paralysis. Greek physician Hippocrates taught students to treat shoulder dislocation by placing a heel in the patient's axilla and pulling on the arm, but this can cause even worse nerve damage and is never done anymore by professionals. Because the shoulder is so easily dislocated, one also should never attempt to move an unconscious or immobilized person by pulling on his or her arm.

The shoulder is stabilized mainly by the biceps brachii muscle on the anterior side of the arm. One of its tendons arises from the *long head* of the muscle, passes through the intertubercular groove of the humerus, and inserts on the superior margin of the glenoid cavity. It acts as a taut strap that presses the humeral head against the glenoid cavity. Four additional muscles help to stabilize this joint: the *supraspinatus*, *infraspinatus*, *teres minor*, and *subscapularis*. Their tendons form the **rotator cuff**, which is fused to the joint capsule on all sides except the inferior (see fig. 10.24). Chapter 10 further describes the rotator cuff and its injuries.

Five principal ligaments also support this joint. Three of them, called the **glenohumeral ligaments**, are relatively weak and sometimes absent. The other two are the **coracohumeral ligament**, which extends from the coracoid process of the scapula to the greater tubercle of the humerus, and the **transverse humeral ligament**, which

extends from the greater to the lesser tubercle of the humerus and forms a tunnel housing the tendon from the long head of the biceps.

Four bursae occur at the shoulder. Their names describe their locations: the **subdeltoid**, **subacromial**, **subcoracoid**, and **subscapular bursae**. The *deltoid* is the large muscle that caps the shoulder, and the other bursae are named for parts of the scapula described in chapter 8.

9.3c The Elbow Joint

The elbow is a hinge joint composed of two articulations: the **humero-ulnar joint** where the trochlea of the humerus joins the trochlear notch of the ulna, and the **humero-radial joint** where the capitulum of the humerus meets the head of the radius (**fig. 9.25**). Both are enclosed in a single joint capsule. On the posterior side of the elbow,

FIGURE 9.25 The Elbow Joint. This region includes two joints that form the elbow hinge—the humeroulnar and humero-radial—and one joint, the radioulnar, not involved in the hinge. (a) Anterior elbow ligaments. (b) Sagittal section, showing joint cavity. (c) Medial elbow ligaments. (d) Lateral elbow ligaments. **APR**

there is a prominent **olecranon bursa** that eases the movement of tendons over the joint. Side-to-side motions of the elbow joint are restricted by a pair of ligaments: the **radial (lateral) collateral ligament** and **ulnar (medial) collateral ligament**.

Another joint occurs in the elbow region, the **proximal radioulnar joint**, but it isn't involved in the hinge. At this joint, the edge of the disclike head of the radius fits into the radial notch of the ulna. It is held in place by the **anular ligament**, which encircles the radial head

and is attached at each end to the ulna. The radial head rotates like a wheel against the ulna as the forearm is pronated or supinated.

9.3d The Hip Joint

The **coxal (hip) joint** is the point where the head of the femur inserts into the acetabulum of the hip bone (**fig. 9.26**). Because the coxal joints bear much of the body's weight, they have deep sockets

(a) Anterior dissection

(b) Lateral view, femur retracted

(c) Anterior view

(d) Posterior view

FIGURE 9.26 The Coxal (Hip) Joint. (a) Anterior view of dissected cadaver hip. (b) Lateral view of hip joint with femur retracted from acetabulum. (c) Anterior hip ligaments. (d) Posterior hip ligaments.

a: Rebecca Gray/McGraw Hill

and are much more stable than the shoulder joint. The depth of the socket is somewhat greater than you see on dried bones because of a horseshoe-shaped ring of fibrocartilage, the **acetabular labrum**, attached to its rim. Dislocations of the hip are therefore rare.

▶▶▶ APPLY WHAT YOU KNOW

Where else in the body is there a structure similar to the acetabular labrum? What do those two locations have in common?

Ligaments that support the coxal joint include the **iliofemoral** and **pubofemoral ligaments** (ILL-ee-oh-FEM-o-rul, PYU-bo-FEM-o-rul) on the anterior side and the **ischiofemoral ligament** (ISS-kee-oh-FEM-o-rul) on the posterior side. The name of each ligament refers to the bones to which it attaches—the femur and the ilium, pubis, or ischium. When you stand up, these ligaments become twisted and pull the head of the femur tightly into the acetabulum. The head of the femur has a conspicuous pit called the **fovea capitis**. The **round ligament**, or **ligamentum teres**²⁷ (TERR-eez), arises here and attaches to the lower margin of the acetabulum. This is a relatively slack ligament, so it is doubtful it plays a significant role in holding the femur in its socket. It does, however, contain an artery that supplies blood to the head of the femur. A **transverse acetabular ligament** bridges a gap in the inferior margin of the acetabular labrum.

9.3e The Knee Joint

The **tibiofemoral (knee) joint** is the largest and most complex diarthrosis of the body (figs. 9.27 and 9.28). It is primarily a hinge joint, but when the knee is flexed it is also capable of slight rotation and lateral gliding. The patella and patellar ligament also articulate with the femur to form a gliding **patellofemoral joint**.

The joint capsule encloses only the lateral and posterior aspects of the knee joint, not the anterior. The anterior aspect is covered by the patella, patellar ligament, and *lateral and medial patellar retinacula* (not illustrated). The retinacula are extensions of the tendon of the *quadriceps femoris muscle*, the large anterior muscle of the thigh. The knee is stabilized mainly by the quadriceps tendon in front and the tendon of the *semimembranosus muscle* on the rear of the thigh. Developing strength in these muscles therefore reduces the risk of knee injury.

The joint cavity contains two C-shaped cartilages called the **lateral** and **medial menisci** (singular, **meniscus**) joined by a **transverse ligament**. The menisci absorb the shock of the body weight jostling up and down on the knee and prevent the femur from rocking from side to side on the tibia.

The posterior **popliteal region** (pop-LIT-ee-ul) of the knee is supported by a complex array of *extracapsular ligaments* external to the joint capsule and two *intracapsular ligaments* within it. The extracapsular ligaments include two collateral ligaments that prevent the knee from rotating when the joint is extended—the **fibular (lateral) collateral ligament** and the **tibial (medial) collateral ligament**—and other ligaments not illustrated.

FIGURE 9.27 The Right Knee, Anterior Dissection. The quadriceps tendon has been cut and folded (reflected) downward to expose the joint cavity and the posterior surface of the patella.

Rebecca Gray/McGraw Hill

The two intracapsular ligaments lie deep within the joint. The synovial membrane folds around them, however, so they're excluded from the fluid-filled synovial cavity. These ligaments cross each other in the form of an X; hence, they are called the **anterior cruciate**²⁸ **ligament (ACL)** (CROO-she-ate) and **posterior cruciate ligament (PCL)**. These are named according to whether they attach to the anterior or posterior side of the tibia, not for their attachments to the femur. When the knee is extended, the ACL is pulled tight and prevents hyperextension. The PCL prevents the femur from sliding off the front of the tibia and prevents the tibia from being displaced backward. The ACL is one of the most common sites of knee injury (see Deeper Insight 9.4).

²⁷teres = round

²⁸cruci = cross; ate = characterized by

FIGURE 9.28 The Right Tibiofemoral (Knee) Joint. (a) Anterior view of knee joint with patella removed. (b) Posterior view. (c) Sagittal section of knee showing joint cavity and bursae. (d) Superior view of tibia showing the menisci. **APR**

▶▶▶ APPLY WHAT YOU KNOW

What structure in the elbow joint serves the same function as the ACL of the knee?

An important aspect of human bipedalism is the ability to lock the knees and stand erect without tiring the extensor

muscles of the leg. When the knee is extended to the fullest degree allowed by the ACL, the femur rotates medially on the tibia. This action locks the knee, and in this state, all the major knee ligaments are twisted and taut. To unlock the knee, the *popliteus* muscle rotates the femur laterally and untwists the ligaments.

DEEPER INSIGHT 9.4

CLINICAL APPLICATION

Knee Injuries and Arthroscopic Surgery

Although the knee can bear a lot of weight, it is highly vulnerable to rotational and horizontal stress, especially when the knee is flexed (as in skiing or running) and receives a blow from behind or from the side. The most common injuries are to a meniscus or the anterior cruciate ligament (ACL). Lateral blows to the knee or body, especially when the foot is firmly planted on the ground, sometimes cause a so-called “unhappy triad” of injuries: tears in the tibial collateral ligament, medial meniscus, and anterior cruciate ligament (**fig. 9.29**). These three structures are strongly interconnected, so an injurious force is easily transferred from one to another. Knee injuries heal slowly because ligaments and tendons have a scanty blood supply and cartilage usually has no blood vessels at all.

The diagnosis and surgical treatment of knee injuries have been greatly improved by *arthroscopy*, a procedure in which the interior of a joint is viewed with a pencil-thin instrument, the *arthroscope*, inserted through a small incision. The arthroscope has a light, a lens, and fiber optics that allow a viewer to see into the cavity and take photographs or video recordings. A surgeon can also withdraw samples of synovial fluid by arthroscopy or inject saline into the joint cavity to expand it and provide a clearer view. If surgery is required, additional small incisions can be made for the surgical instruments and the procedures can be observed through the arthroscope or on a monitor. Arthroscopic surgery produces much less tissue damage than conventional surgery and enables patients to recover more quickly.

Orthopedic surgeons now often replace a damaged ACL with a graft from the patellar ligament or a hamstring tendon. The surgeon “harvests” a strip from the middle of the patient’s ligament (or tendon), drills a hole into the femur and tibia within the joint cavity, threads the ligament through the holes, and fastens it with biodegradable screws. The grafted ligament is more taut and “competent” than the damaged ACL. It becomes ingrown with blood vessels and serves as a substrate for the deposition of more collagen, which further strengthens it in time. Following arthroscopic ACL reconstruction, a patient typically must use crutches for 7 to 10 days and undergo physical therapy for 6 to 10 weeks, followed by self-directed exercise therapy. Healing is completed in about 9 months.

The knee joint has about 13 bursae. Four of these are anterior: the **superficial infrapatellar**, **suprapatellar**, **prepatellar**, and **deep infrapatellar**. Located in the popliteal region are the *popliteal bursa* and *semimembranosus bursa* (not illustrated). At least seven more bursae are found on the lateral and medial sides of the knee joint. From figure 9.28c, your knowledge of the relevant word elements (*infra-*, *supra-*, *pre-*), and the terms *superficial* and *deep*, you should be able to work out the reasoning behind most of these names and develop a system for remembering the locations of these bursae.

FIGURE 9.29 The “Unhappy Triad” of Knee Injuries.

9.3f The Ankle Joint

The **talocrural**²⁹ (ankle) joint includes two articulations—a medial joint between the tibia and talus and a lateral joint between the fibula and talus, both enclosed in one joint capsule (**fig. 9.30**). The malleoli of the tibia and fibula overhang the talus on each side like a cap and prevent most side-to-side motion. The ankle therefore has a more restricted range of motion than the wrist.

²⁹*talo* = ankle; *crural* = pertaining to the leg

FIGURE 9.30 The Talocrural (Ankle) Joint and Ligaments of the Right Foot. (a) Lateral view. (b) Lateral ligaments in dissected cadaver ankle. (c) Medial view. (d) Posterior view. **APR**

b: Christine Eckel/McGraw Hill

The ligaments of the ankle include (1) **anterior and posterior tibiofibular ligaments**, which bind the tibia to the fibula; (2) a multipart **medial (deltoid³⁰) ligament**, which binds the tibia to the foot on the medial side; and (3) a multipart **lateral (collateral) ligament**, which binds the fibula to the foot on the lateral side. The **calcaneal (Achilles) tendon** extends from the calf muscles to the calcaneus. It plantarflexes the foot and limits dorsiflexion. Plantar flexion is limited by extensor tendons on the anterior side of the ankle and by the anterior part of the joint capsule.

Sprains (torn ligaments and tendons) are common at the ankle, especially when the foot is suddenly inverted or everted to excess. They are painful and usually accompanied by immediate swelling. They are best treated by immobilizing the joint and reducing swelling

with an ice pack, but in extreme cases may require a cast or surgery. Sprains and other joint disorders are briefly described in **table 9.1**.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- 12.** What keeps the mandibular condyle from slipping out of its fossa in a posterior direction?
- 13.** Explain how the biceps brachii tendon braces the shoulder joint.
- 14.** Identify the three joints found at the elbow and name the movements in which each joint is involved.
- 15.** What keeps the femur from slipping backward off the tibia?
- 16.** What keeps the tibia from slipping sideways off the talus?

³⁰delt = triangular, Greek letter delta (Δ); oid = resembling

TABLE 9.1	Some Common Joint Disorders
Arthritis	Broad term embracing more than 100 types of joint rheumatism.
Bursitis	Inflammation of a bursa, usually due to overuse of a joint.
Dislocation	Displacement of a bone from its normal position at a joint, usually accompanied by a sprain of the adjoining connective tissues. Most common at the fingers, thumb, shoulder, and knee.
Gout	A hereditary disease, most common in men, in which uric acid crystals accumulate in the joints and irritate the articular cartilage and synovial membrane. Causes gouty arthritis, with swelling, pain, tissue degeneration, and sometimes fusion of the joint. Most commonly affects the great toe.
Rheumatism	Broad term for any pain in the supportive and locomotory organs of the body, including bones, ligaments, tendons, and muscles.
Sprain	Torn ligament or tendon, sometimes with damage to a meniscus or other cartilage.
Strain	Painful overstretching of a tendon or muscle without serious tissue damage. Often results from inadequate warm-up before exercise.
Synovitis	Inflammation of a joint capsule, often as a complication of a sprain.
Tendinitis	A form of bursitis in which a tendon sheath is inflamed.
You can find other joint disorders in the following places:	
Temporomandibular joint (TMJ) dysfunction in Deeper Insight 9.2; jaw dislocation in section 9.3a; shoulder dislocation in Deeper Insight 9.3; knee injuries in Deeper Insight 9.4; arthritis in Deeper Insight 9.5; hip dislocation in section 9.3d; and rotator cuff injury in Deeper Insight 10.4.	

DEEPER INSIGHT 9.5

CLINICAL APPLICATION

Arthritis and Artificial Joints

Arthritis³¹ is a broad term for pain and inflammation of a joint and embraces more than a hundred different diseases of largely obscure or unknown causes. In all of its forms, it is the most common crippling disease in the United States; nearly everyone past middle age develops arthritis to some degree. Physicians who treat arthritis and other joint disorders are called *rheumatologists*.

The most common form of arthritis is *osteoarthritis (OA)*, also called “wear-and-tear arthritis” because it is apparently a normal consequence of years of wear on the joints. As joints age, the articular cartilages soften and degenerate. As the cartilage becomes roughened by wear, joint movement may be accompanied by crunching or crackling sounds called *crepitus*. OA affects especially the fingers, intervertebral joints, hips, and knees. As the articular cartilage wears away, exposed bone tissue often develops spurs that grow into the joint cavity, restrict movement, and cause pain. OA rarely occurs before age 40, but it affects about 85% of people older than 70, especially those who are overweight. It usually doesn’t cripple, but in severe cases it can immobilize the hip.

Rheumatoid arthritis (RA), which is far more severe than osteoarthritis, results from an autoimmune attack against the joint tissues. It begins when the body produces antibodies to fight an infection. Failing to recognize the body’s own tissues, a misguided antibody known as *rheumatoid factor* also attacks the synovial membranes. Inflammatory cells accumulate in the synovial fluid and produce enzymes that degrade the articular cartilage. The synovial membrane thickens and adheres to the articular cartilage, fluid accumulates in the joint capsule, and the capsule is invaded by fibrous connective tissue. As articular

cartilage degenerates, the joint begins to ossify, and sometimes the bones become solidly fused and immobilized, a condition called *ankylosis*³² (**fig. 9.31**). The disease tends to develop symmetrically—if the right wrist or hip develops RA, so does the left.

Rheumatoid arthritis is named for the fact that symptoms tend to flare up and subside (go into remission) periodically.³³ It affects women far more often than men, and because RA typically begins as early as age 30 to 40, it can cause decades of pain and disability. There is no cure, but joint damage can be slowed with hydrocortisone or other steroids. Because long-term use of steroids weakens the bone, however, aspirin is the treatment of first choice to control the inflammation. Physical therapy is also used to preserve the joint’s range of motion and the patient’s functional ability.

Arthroplasty,³⁴ a treatment of last resort, is the replacement of a diseased joint with an artificial device called a *joint prosthesis*.³⁵ Joint prostheses were first developed to treat injuries in World War II and the Korean War. Total hip replacement (THR), first performed in 1963 by English orthopedic surgeon Sir John Charnley, is now the most common orthopedic procedure for the elderly. The first knee replacements were performed in the 1970s. Joint prostheses are now available for finger, shoulder, and elbow joints, as well as the hip and knee. Arthroplasty is performed on over 250,000 patients per year in the United States, primarily to relieve pain and restore function in elderly people with OA or RA.

³¹*arthr* = joint; *itis* = inflammation

³²*ankyl* = bent, crooked; *osis* = condition

³³*rheumat* = tending to change

³⁴*arthro* = joint; *plasty* = surgical repair

³⁵*prosth*e = something added

Arthroplasty presents ongoing challenges for biomedical engineering. An effective prosthesis must be strong, nontoxic, and corrosion-resistant. In addition, it must bond firmly to the patient's bones and enable a normal range of motion with a minimum of friction. The heads of long bones are usually replaced with prostheses made of very hard ceramics such as titanium carbide, cobalt–chromium, or other metal alloys. Joint sockets are made of polyethylene (**fig. 9.32**). Prostheses are bonded to the patient's bone with screws or bone cement.

Improvements in technology have resulted in long-lasting prostheses. Over 75% of artificial knees last 20 years, nearly 85% last 15 years, and over 90% last 10 years. The most common form of failure is detachment of the prosthesis from the bone. This problem has been reduced by using *porous-coated prostheses*, which become infiltrated by the patient's own bone and create a firmer bond. A prosthesis isn't as strong as a natural joint, however, and is not an option for many young, active patients.

Arthroplasty has been greatly improved by *computer-assisted design and manufacture (CAD/CAM)*. A computer scans X-rays from the patient and presents several design possibilities for review. Once a design is selected, the computer generates a program to operate the machinery that produces the prosthesis. CAD/CAM has reduced the waiting period for a prosthesis from 12 weeks to about 2 weeks and has lowered the cost dramatically.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

9.1 Joints and Their Classification

1. The fundamental definition of *joint (articulation)* and why it can't be defined as a point at which one bone moves relative to an adjacent bone
2. Relationships and differences between the sciences of arthrology, kinesiology, and biomechanics
3. The typical system for naming most joints after the bones they involve; examples of this
4. Basic criteria for classifying joints
5. Characteristics and examples of bony joints (synostoses)
6. Characteristics of fibrous joints (synarthroses) and each of their subclasses, with examples
7. Characteristics of cartilaginous joints (amphiarthroses) and each of their subclasses, with examples

9.2 Synovial Joints

1. The definition and anatomical features of a *synovial joint (diarthrosis)*, examples of this type, and why this type is of greatest interest for kinesiology
2. General anatomy of tendons, ligaments, bursae, and tendon sheaths, and their contributions to joint function

3. Three essential components of a lever
4. The meaning of *mechanical advantage (MA)*; how the *MA* of a lever can be determined from measurements of its effort and resistance arms; and the respective advantages of levers in which the *MA* is greater than or less than 1.0
5. Comparison of first-, second-, and third-class levers, and anatomical examples of each
6. Variables that determine a joint's range of motion (*ROM*), and the clinical relevance of *ROM*
7. Axes of rotation and degrees of freedom in joint movement, and how this relates to the classification of joints as monaxial, biaxial, or multiaxial
8. Six kinds of synovial joints; how each is classified as monaxial, biaxial, or multiaxial; imperfections in this classification; and examples of each type in the body
9. The concept of zero position and how it relates to the description of joint function
10. Examples of each of the following limb movements, including an ability to describe or demonstrate them: flexion, extension, abduction, adduction, circumduction, medial rotation, and lateral rotation
11. The same for supination, pronation, ulnar flexion, and radial flexion of the forearm and hand, and opposition, reposition, abduction, and adduction of the thumb

12. The same for flexion, extension, hyperextension, and lateral flexion of the spine, and right and left rotation of the trunk
13. The same for elevation, depression, protraction, retraction, and lateral and medial excursion of the mandible
14. The same for dorsiflexion, plantar flexion, inversion, eversion, pronation, and supination of the foot

9.3 Anatomy of Selected Diarthroses

1. Features of the jaw (temporomandibular) joint including the mandibular condyle, mandibular fossa, synovial cavity, articular disc, and principal ligaments
2. Features of the shoulder (glenohumeral) joint including the humeral head, glenoid cavity and labrum, five major ligaments and four bursae, and tendons of the biceps brachii and four rotator cuff muscles
3. Features of the elbow; the three joints that occur here; the olecranon bursa and four major ligaments
4. Features of the hip (coxal) joint including the femoral head, fovea capitis, acetabulum and labrum, and five principal ligaments
5. Features of the knee (tibiofemoral and patellofemoral joints), including the menisci, cruciate and other ligaments, and four major bursae around the patella
6. Features of the ankle (talocrural) joint, including the malleoli, calcaneal tendon, and major ligaments

► Testing Your Recall

1. Internal and external rotation of the humerus is made possible by a _____ joint.
 - a. pivot
 - b. condylar
 - c. ball-and-socket
 - d. saddle
 - e. hinge
2. Which of the following is the least movable?
 - a. a diarthrosis
 - b. a synostosis
 - c. a symphysis
 - d. a synovial joint
 - e. a condylar joint
3. Which of the following movements are unique to the foot?
 - a. dorsiflexion and inversion
 - b. elevation and depression
 - c. circumduction and rotation
 - d. abduction and adduction
 - e. opposition and reposition

Answers in Appendix A

STUDY GUIDE

4. Which of the following joints cannot be circumducted?
 - a. carpometacarpal
 - b. metacarpophalangeal
 - c. glenohumeral
 - d. coxal
 - e. interphalangeal
5. Which of the following terms denotes a general condition that includes the other four?
 - a. gout
 - b. arthritis
 - c. rheumatism
 - d. osteoarthritis
 - e. rheumatoid arthritis
6. In the adult, the ischium and pubis are united by
 - a. a synchondrosis.
 - b. a diarthrosis.
 - c. a synostosis.
 - d. an amphiarthrosis.
 - e. a symphysis.
7. In a second-class lever, the effort
 - a. is applied to the end opposite the fulcrum.
 - b. is applied to the fulcrum itself.
 - c. is applied between the fulcrum and resistance.
 - d. always produces an *MA* less than 1.0.
 - e. is applied on one side of the fulcrum to move a resistance on the other side.
8. Which of the following joints has anterior and posterior cruciate ligaments?
 - a. the shoulder
 - b. the elbow
 - c. the hip
 - d. the knee
 - e. the ankle
9. To bend backward at the waist involves _____ of the vertebral column.
 - a. rotation
 - b. hyperextension
 - c. dorsiflexion
 - d. abduction
 - e. flexion
10. The rotator cuff includes the tendons of all of the following muscles *except*
 - a. the subscapularis.
 - b. the supraspinatus.
 - c. the infraspinatus.
 - d. the biceps brachii.
 - e. the teres minor.
11. The lubricant of a diarthrosis is called _____.
12. A fluid-filled sac that eases the movement of a tendon over a bone is called a/an _____.
13. A _____ joint allows one bone to swivel on another.
14. _____ is the science of movement.
15. The joint between a tooth and the mandible is called a/an _____.
16. In a _____ suture, the articulating bones have interlocking wavy margins, somewhat like a dovetail joint in carpentry.
17. In kicking a football, what type of action does the knee joint exhibit?
18. The angle through which a joint can move is called its _____.
19. The menisci of the knee are functionally similar to the _____ of the temporomandibular joint.
20. At the ankle, both the tibia and fibula articulate with what tarsal bone?

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|------------|-----------|-------------|
| 1. ab- | 3. -ate | 7. kinesio- |
| 2. arthro- | 4. cruci- | 8. men- |
| | 5. cruro- | 9. supin- |
| | 6. -duc | 10. -trac |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|--|---|--|
| 1. More people get rheumatoid arthritis than osteoarthritis. | 4. Menisci occur in the elbow and knee joints. | 8. The knuckles are amphiarthroses. |
| 2. A doctor who treats arthritis is called a kinesiologist. | 5. Reaching behind you to take something out of your hip pocket involves flexion of the shoulder. | 9. Synovial fluid is secreted by the bursae. |
| 3. Synovial joints are also known as synarthroses. | 6. The cruciate ligaments are in the feet. | 10. Like most ligaments, the periodontal ligaments attach one bone (the tooth) to another (the mandible or maxilla). |
| | 7. The femur is held tightly in the acetabulum mainly by the round ligament. | |

STUDY GUIDE

► Testing Your Comprehension

1. All second-class levers produce a mechanical advantage greater than 1.0 and all third-class levers produce a mechanical advantage less than 1.0. Explain why.
2. For each of the following joint movements, state what bone the axis of rotation passes through and which of the three anatomical planes contains the axis of rotation. You may find it helpful to produce some of these actions on an articulated laboratory skeleton so you can more easily visualize the axis of rotation. (a) Plantar flexion; (b) flexion of the hip; (c) abduction of the thigh; (d) flexion of the knee; (e) flexion of the first interphalangeal joint of the index finger. (Do not bend the fingers of a wired laboratory skeletal hand, because they can break off.)
3. In order of occurrence, list the joint actions (flexion, pronation, etc.) and the joints where they would occur as you (a) sit down at a table, (b) reach out and pick up an apple, (c) take a bite, and (d) chew it. Assume that you start in anatomical position.
4. The deltoid muscle inserts on the deltoid tuberosity of the humerus and abducts the arm. Imagine a person holding a weight in the hand and abducting the arm. On a laboratory skeleton, identify the fulcrum; measure the effort arm and resistance arm; determine the mechanical advantage of this movement; and determine which of the three lever types the upper limb acts as when performing this movement.
5. List the six types of synovial joints, and for each one, if possible, identify a joint in the upper limb and a joint in the lower limb that fall into each category. Which of these six joints has/have no examples in the lower limb?

Colorized MRI scan showing muscles of the lumbar, pelvic, and upper femoral regions

Simon Fraser/Science Source

Module 6: Muscular System

BRUSHING UP

- Understanding of the skeletal muscles depends on a thorough knowledge of skeletal anatomy (chapter 8), including not just the bones but also their surface features (table 8.2), many of which are muscle attachments.
- This chapter describes the movements produced by muscles, called their *actions*, using the terminology of joint movements in section 9.2c.

Muscles constitute nearly half of the body's weight and occupy a place of central interest in several fields of health care and fitness. Physical and occupational therapists must be well acquainted with the muscular system to plan and carry out rehabilitation programs. Athletes and trainers, dancers and acrobats, and amateur fitness enthusiasts follow programs of resistance training to strengthen individual muscle groups through movement regimens based on knowledge of muscle, bone, and joint anatomy. Nurses employ their knowledge of the muscular system to give intramuscular injections correctly and to safely and effectively move patients who are physically incapacitated. Gerontological nurses are keenly aware of how deeply a person's muscular condition affects the quality of life in old age. The muscular system is highly important to biomedical disciplines even beyond the scope of the movement sciences. For example, it is the primary source of body heat in the moving individual, and loss of muscle mass can be a contributing factor in diabetes mellitus.

The muscular system is closely related to what we have covered in the preceding chapters. After this, we will examine the mechanisms of muscle contraction at the cellular and molecular levels in chapter 11, and chapter 12 will shed light on the relationship of the muscles to the nerves that control them.

10.1 Structural and Functional Organization of Muscles

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the various functions of muscular tissue;
- describe the connective tissue components of a muscle and their relationship to the internal organization of a muscle and compartmentalization of muscle groups;
- relate muscle fascicles to the shapes and relative strengths of muscles;
- name the types of muscle–bone attachments and explain the shortcoming of calling their attachments *origins* and *insertions*;
- distinguish between intrinsic and extrinsic muscles;
- describe the ways muscles work in groups to aid, oppose, and moderate each other's actions;
- describe in general terms the nerve and blood supply to skeletal muscles; and
- explain how the Latin names of muscles aid in visualizing and remembering them.

The word *muscle*¹ means “little mouse,” and apparently was coined by one of the ancient Greek authorities who thought that skeletal muscles rippling under the skin resembled scurrying mice. As we saw in chapter 5, however, there are three kinds of muscle—skeletal, cardiac, and smooth. Despite their differences, all muscle is specialized for one fundamental purpose: to convert the chemical energy of ATP into the mechanical energy of motion. Muscle cells exert force on other tissues and organs, either to produce desirable movements or to prevent undesirable ones.

10.1a The Functions of Muscles

Collectively, the three types of muscle serve the following functions:

- **Movement.** Muscles enable us to move from place to place and to move individual body parts; they move body contents in the course of breathing, blood circulation, feeding and digestion, defecation, urination, and childbirth; and they serve various roles in communication—speech, writing, facial expressions, and other body language.
- **Stability.** Muscles maintain posture by preventing unwanted movements. Some are called *antigravity muscles* because, at least part of the time, they resist the pull of gravity and prevent us from falling or slumping over. Many muscles also stabilize the joints by maintaining tension on tendons and bones.
- **Control of body openings and passages.** Muscles encircling the mouth serve not only for speech but also for food intake and retention of food while chewing. In the eyelid and pupil, they regulate the admission of light to the eye. Internal muscular rings control the movement of food, bile, blood, and other materials within the body. Muscles encircling the urethra and anus control the elimination of waste. (Some of these muscles are called *sphincters*, but not all; this is clarified later.)
- **Heat production (thermogenesis).** The skeletal muscles produce 20% to 30% of the body's heat at rest and up to 85% during exercise. This body heat is vital to the functioning of enzymes and therefore to all metabolism. When it's lacking, people die of hypothermia.
- **Hormone secretion.** Exercised muscles secrete hormones (*myokines*) that stimulate glucose synthesis by the liver and breakdown of visceral (body-cavity) fat.
- **Glycemic control.** This means the regulation of blood glucose concentration within its normal range. The skeletal muscles absorb, store, and use a large share of one's glucose and play a highly significant role in stabilizing its blood concentration. In old age, in obesity, and when muscles become deconditioned and weakened, people suffer an increased risk of type 2 diabetes mellitus because of the decline in this glucose-buffering function.

The rest of this chapter concerns only the skeletal muscles. The term **muscular system** refers only to these, not the other two types of muscle. The study of skeletal muscles is called **myology**.² There are about 600 muscles in the human muscular system, but fortunately you aren't expected to learn 600 names! Many have

¹*mus* = mouse; *cle* = little

²*myo* = muscle; *logy* = study of

repetitious names, such as the right and left muscles of the same name and muscle series between ribs and vertebrae. This chapter describes fewer than one-third of the muscles. Smooth and cardiac muscle are discussed in chapters 11 and 19.

10.1b Muscle Connective Tissues, Fascicles, and Compartments

A skeletal muscle consists of more than muscular tissue. It also includes connective tissue, nerves, and blood vessels. The connective tissue components, from the smallest to largest and from deep to superficial, are as follows (**fig. 10.1**):

- **Endomysium**³ (EN-doe-MIZ-ee-um). This is a thin sleeve of loose connective tissue that surrounds each muscle fiber. It creates room for blood capillaries and nerve fibers to reach every muscle fiber, ensuring that no muscle cell is without stimulation and nourishment. The endomysium also provides the extracellular chemical environment for the muscle fiber and its associated nerve ending. Excitation of a muscle fiber is based on the exchange of calcium, sodium, and potassium ions between the endomysial tissue fluid and the nerve and muscle fibers.

³endo = within; mys = muscle

FIGURE 10.1 Connective Tissues of a Muscle. (a) The muscle–bone attachment and subdivisions of a skeletal muscle. (b) A cross section of the thigh showing the relationship of neighboring muscles to fasciae and bone. (c) Muscle fascicles in the tongue. Vertical fascicles passing between the superior and inferior surfaces of the tongue are seen alternating with cross-sectioned horizontal fascicles that pass from the rear to the tip of the tongue. A fibrous perimysium can be seen between the fascicles, and endomysium can be seen between the muscle fibers within each fascicle. (c.s. = cross section; l.s. = longitudinal section)

c: Victor Eroschenko

FIGURE 10.2 Classification of Muscles According to Fascicle Orientation. The fascicles are the grain visible in each illustration. Muscle types are named across the top and an example of each type across the bottom.

- **Perimysium.**⁴ This is a thicker connective tissue sheath that wraps muscle fibers together in bundles called **fascicles**⁵ (FASS-ih-culs). A fascicle typically comprises 20 to 60 muscle fibers. Fascicles are visible to the naked eye as parallel strands—the grain in a cut of meat; if you pull apart “fork-tender” roast beef, it separates along these fascicles. The perimysium carries the larger nerves and blood vessels as well as stretch receptors called muscle spindles.
- **Epimysium.**⁶ This is a fibrous sheath that surrounds the entire muscle. On its outer surface, the epimysium grades into the fascia, and its inner surface issues projections between the fascicles to form the perimysium.
- **Fascia**⁷ (FASH-ee-uh). This is a sheet of connective tissue that separates neighboring muscles or muscle groups from each other and from the subcutaneous tissue. Muscles are grouped in *compartments* separated from each other by fasciae.

The *fascicles* defined by the perimysium are oriented in a variety of ways that determine the strength of a muscle and the direction in which it pulls. According to fascicle orientation, muscles are classified as shown in **figure 10.2**.

- **Fusiform**⁸ muscles are thick in the middle, with fascicles converging on each tapered end. The *biceps brachii* of the arm and *gastrocnemius* of the calf are examples of this type. Muscle strength is proportional to the diameter of a muscle at its thickest point, and fusiform muscles are relatively strong.
- **Parallel muscles** have a fairly uniform width and parallel fascicles. Some of these muscles are elongated straps, such as the *rectus abdominis* of the abdomen, *sartorius* of the thigh, and *zygomaticus major* of the face. Others are more squarish and are called *quadrilateral* (four-sided) muscles, such as the *masseter* of the jaw. Parallel muscles can span long distances,

such as from hip to knee, and they shorten more than other muscle types. However, having fewer muscle fibers than a fusiform muscle of the same mass, they produce less force.

- **Triangular (convergent) muscles** are fan-shaped—broad at one end with fascicles converging on the other, narrower end. Examples include the *pectoralis major* in the chest and the *temporalis* on the side of the head. Despite their small localized insertions on a bone, these muscles are relatively strong because they contain a large number of fibers in the wider part of the muscle.
- **Pennate**⁹ muscles are feather-shaped. Their fascicles insert obliquely on a tendon that runs the length of the muscle, like the shaft of a feather. There are three types of pennate muscles: *unipennate*, in which all fascicles approach the tendon from one side (for example, the *palmar interosseous muscles* of the hand and *semimembranosus* of the thigh); *bipennate*, in which fascicles approach the tendon from both sides (for example, the *rectus femoris* of the thigh); and *multipennate*, shaped like a bunch of feathers with their quills converging on a single point (for example, the *deltoid* of the shoulder). These muscles generate more force than the preceding types because they fit more muscle fibers into a given length of muscle.
- **Circular muscles (sphincters)** have fascicles in rings around certain body openings and passages. When they contract, they constrict the opening and tend to prevent the passage of material through it. Examples include the *orbicularis oculi* of the eyelids and the *external urethral* and *anal sphincters*. Smooth muscle can also form sphincters—for example, the *pyloric valve* at the passage from the stomach to the small intestine and some sphincters of the urinary tract and anal canal.

The fasciae are not components of the muscles themselves, but package groups of functionally related muscles into **muscle compartments** (**fig. 10.3**) and stand between the muscles and the overlying

⁴*peri* = around; *mys* = muscle

⁵*fasc* = bundle; *icle* = little

⁶*epi* = upon, above; *mys* = muscle

⁷*fascia* = band

⁸*fusi* = spindle; *form* = shape

⁹*penna* = feather; *ate* = characterized by

FIGURE 10.3 Muscle Compartments. A cross section of the left leg slightly above midcalf, oriented the same way as the reader's left leg.

hypodermis and skin. A compartment also contains the nerves and blood vessels that supply the muscle group. Such compartmentalization occurs in the thoracic and abdominal walls, pelvic floor, and limbs. Some of these fasciae are particularly thick and are called **intermuscular septa**. The tight binding of muscles by these fasciae contributes to a clinical problem described in Deeper Insight 10.1.

DEEPER INSIGHT 10.1 CLINICAL APPLICATION

Compartment Syndrome

Muscle compartments are very snugly contained in their fasciae. If a blood vessel in a compartment is damaged by overuse or contusion (a bruising injury), blood and tissue fluid accumulate in the compartment. The inelastic fascia prevents the compartment from expanding to relieve the pressure. Mounting pressure on the muscles, nerves, and blood vessels can trigger a sequence of degenerative events called **compartment syndrome**. Blood flow to the compartment is obstructed by pressure on its arteries. If *ischemia* (poor blood flow) persists for more than 2 to 4 hours, nerves begin to die, and after 6 hours, so does muscle tissue. Nerves can regenerate after the pressure is relieved, but muscle necrosis is irreversible. The breakdown of muscle releases myoglobin into the blood. *Myoglobinuria*, the presence of myoglobin in the urine, gives the urine a dark color and is one of the key signs of compartment syndrome and some other degenerative muscle disorders. Compartment syndrome is treated by immobilizing and resting the limb and, if necessary, making an incision (*fasciotomy*) to relieve the pressure.

10.1c Muscle Attachments

Connective tissue components of a muscle emerge from it as collagenous fibers that continue into its tendon or other bone attachment, then into the periosteum and matrix of the bone, creating very strong structural continuity from muscle to bone. Some muscles insert not on bones but on the fascia or tendon of another muscle or on collagen fibers of the dermis. The distal tendon of the biceps brachii, for example, inserts partly on the fascia of the forearm. Many muscles of the face insert in the skin of the lips, eyelids, and other areas, enabling them to produce expressions such as a smile or a wink.

Direct and Indirect Attachments

Muscles have two forms of attachment to bones—direct and indirect. In a **direct (fleshy) attachment**, such as in the *brachialis* and the lateral head of the *triceps brachii* in **figure 10.4**, there is so little separation between muscle and bone that to the naked eye, the red muscular tissue seems to emerge directly from the bone. At a microscopic level, however, the muscle fibers stop slightly short of the bone and the gap between muscle and bone is spanned by collagen fibers.

In an **indirect attachment**, the muscle ends visibly short of its bony destination, and the gap is bridged by a fibrous cord or band called a **tendon**. See, for example, the two ends of the biceps brachii in **figure 10.4** and the photographs of tendons in **figures 10.32b** and **10.37**. You can easily palpate tendons and feel their texture just above your heel (your *calcaneal* or *Achilles tendon*) and on the anterior side of your wrist (tendons of the *palmaris longus* and *flexor carpi radialis* muscles).

FIGURE 10.4 Synergistic and Antagonistic Muscle Pairs. The biceps brachii and brachialis muscles are synergists in elbow flexion. The triceps brachii is an antagonist of those two muscles and is the prime mover in elbow extension.

? Which of these muscles have direct attachments to the bones, and which have indirect attachments?

In some cases, the tendon is a broad sheet called an **aponeurosis**¹⁰ (AP-oh-new-RO-sis). This term originally referred to the tendon located beneath the scalp (hence the word root *neuro-*), but now it also refers to similar tendons associated with certain abdominal, lumbar, hand, and foot muscles. For example, the palmaris longus tendon passes through the wrist and then expands into a fanlike *palmar aponeurosis* beneath the skin of the palm (see fig. 10.29a).

In some places, groups of tendons from separate muscles pass under a band of connective tissue called a **retinaculum**.¹¹ One of these covers each surface of the wrist like a bracelet, for example. The tendons of several forearm muscles pass under them on their way to the hand (see figs. 5.13, 10.29a).

Moving and Stationary Attachments

Since most muscles span at least one joint and attach to a different bone at each end, their contraction moves one bone relative to the other. Traditionally, the attachment at the stationary end has been called the **origin** of the muscle and the attachment at the moving end has been called the **insertion**. *Gray's Anatomy* and other current authorities, however, have largely abandoned the *origin* and *insertion* terms because they are imperfect and sometimes misleading. There

are many cases in which the moving and nonmoving ends of the muscle are reversed when different actions are performed.

Consider the difference, for example, in the relative movements of the humerus and ulna when flexing the elbow to lift barbells as compared with flexing it to perform chin-ups or scale a climbing wall. In weight lifting, the arm is relatively stationary and the forearm performs most of the motion, so the proximal end of the biceps would be considered the origin and its distal end the insertion. In chin-ups, by contrast, the forearm is more stationary and the arm moves more to lift the body, so the origin and insertion, if defined by relative motion, would be reversed.

Also consider the *quadriceps femoris* muscle on the anterior side of the thigh. It is a powerful extensor of the knee, connected at its proximal end mainly to the femur and at its distal end to the tibia, just below the knee. If you kick a soccer ball, the tibia moves more than the femur, so the tibia would be considered the insertion of the quadriceps and the femur would be considered its origin. But as you sit down in a chair, the femur moves more than the tibia, which remains relatively stationary. The quadriceps then acts as a brake so you don't sit down too abruptly and hard. By the foregoing definitions, the tibia would now be considered the origin of the quadriceps and the femur would be its insertion.

Some authorities therefore now speak of proximal and distal, medial and lateral, or superior and inferior muscle attachments, but no single system of naming applies throughout the body.

Even though *origin–insertion* terminology is becoming obsolete, it may still appear in some courses, board examinations, and other places. Therefore, for each muscle in tables 10.1 through 10.16, there are two bullet points (•) in the “Skeletal Attachments” column. The first bullet point denotes what has traditionally been called that muscle's origin, and the second one its insertion, enabling you to study the anatomy that way if your course so requires. These are aptly called skeletal attachments in the tables, because that applies to *nearly* all of them. Notwithstanding the table headers, though, be aware that a few of these muscles attach not to bone but to dermis, fasciae, or other soft connective tissues.

10.1d Functional Groups of Muscles

Consider the human hand. It requires subtle, finely controlled movement for such tasks as handwriting and keyboarding, but also powerful movements for such actions as climbing and tightly grasping tools. Muscles big enough to provide such power would be too bulky to fit within the hand itself, so they lie in the forearm and connect to the metacarpal bones and phalanges through long slender tendons that pass through the wrist. The more subtle movements are controlled by small muscles located entirely within the hand. Any muscle contained entirely within a region of interest is called an **intrinsic muscle**. A muscle that acts upon a designated organ or region such as the hand, but arises from another region such as the forearm, is called an **extrinsic muscle**. The intrinsic–extrinsic distinction applies not only to the hand but also to the muscles of the tongue, larynx, back, foot, and other regions. You will find several muscles classified this way in the tables in this chapter.

The effect produced by a muscle, whether it is to produce or prevent a movement, is called its **action**. Skeletal muscles seldom

¹⁰*apo* = upon, above; *neuro* = nervous system, brain

¹¹*retinac* = retainer, bracelet; *cul* = little

act independently; instead, they function in groups whose combined actions produce the coordinated control of a joint. Muscles can be classified into four categories according to their actions, but it must be stressed that a particular muscle can act in a certain way during one joint action and in a different way during other actions of the same joint. Furthermore, the action of a given muscle depends on what other muscles are doing. For example, the *gastrocnemius* of the posterior calf usually flexes the knee, but if the *quadriceps* of the anterior thigh prevents knee flexion, the *gastrocnemius* flexes the ankle, causing plantar flexion. The following categories of muscle action are exemplified by muscles that act on the elbow (fig. 10.4):

1. The **prime mover (agonist)** is the muscle that produces most of the force during a particular joint action. In flexing the elbow, for example, the prime mover is the *brachialis*.
2. A **synergist**¹² (SIN-ur-jist) is a muscle that aids the prime mover. Two or more synergists acting on a joint can produce more power than a single larger muscle. The *biceps brachii*, for example, overlies the *brachialis* and works with it as a synergist to flex the elbow. The actions of a prime mover and its synergist aren't necessarily identical and redundant. If the prime mover worked alone at a joint, it could cause rotation or other undesirable movements of a bone. A synergist may stabilize a joint and restrict these movements, or modify the direction of a movement so that the action of the prime mover is more coordinated and specific.
3. An **antagonist**¹³ is a muscle that opposes the prime mover. In some cases, it relaxes to give the prime mover almost complete control over an action. More often, however, the antagonist maintains some tension on a joint and thus limits the speed or range of the prime mover, preventing excessive movement, joint injury, or inappropriate actions. If you extend your arm to reach out and pick up a cup of tea, for example, your *triceps brachii* serves as the prime mover of elbow extension, and your *brachialis* acts as an antagonist to slow the extension and stop it at the appropriate point. If you extend your arm rapidly to throw a dart, however, the *brachialis* must be quite relaxed. The *brachialis* and *triceps* represent an **antagonistic pair** of muscles that act on opposite sides of a joint. We need antagonistic pairs at a joint because a muscle can only pull, not push—for example, a single muscle can't flex *and* extend the elbow. Which member of the pair acts as the prime mover depends on the motion under consideration. In flexion of the elbow, the *brachialis* is the prime mover and the *triceps* is the antagonist; when the elbow is extended, their roles are reversed.
4. A **fixator** is a muscle that prevents a bone from moving. To *fix* a bone means to hold it steady, allowing another muscle attached to it to pull on something else. For example, consider again the flexion of the elbow by the *biceps brachii*. The *biceps* originates on the scapula, crosses both the shoulder and elbow joints, and inserts on the radius and forearm fascia. The scapula is loosely attached to the axial skeleton, so when the *biceps* contracts, it seems that it would pull the scapula

laterally. However, there are fixator muscles (the *rhomboids*) that attach the scapula to the vertebral column (see fig. 10.18). They contract at the same time as the *biceps*, holding the scapula firmly in place and ensuring that the force generated by the *biceps* moves the radius rather than the scapula.

10.1e Innervation and Blood Supply

A skeletal muscle cannot contract unless it is stimulated by a nerve fiber. If its nerve is severed, the muscle is paralyzed. The nerve that supplies a given muscle is called its **innervation**. Knowing the innervation to each muscle enables clinicians to diagnose nerve, spinal cord, and brainstem injuries from their effects on muscle function, and to set realistic goals for rehabilitation. The innervations described in this chapter will be more meaningful after you have studied the peripheral nervous system (chapters 13 and 14), but a brief orientation will be helpful here. The muscles are innervated by nerve branches that arise from these two groups:

- **Spinal nerves** arise from the spinal cord, emerge through the intervertebral foramina, and supply branches to muscles below the neck. Spinal nerves are identified by letters and numbers that refer to the adjacent vertebrae—for example, T6 for the sixth thoracic nerve and S2 for the second sacral nerve. Immediately after emerging from an intervertebral foramen, each spinal nerve branches into a *posterior* and *anterior ramus*. You will note references to nerve numbers and rami in many of the muscle tables. The term *plexus* in some of the tables refers to weblike networks of spinal nerves adjacent to the vertebral column. All of the spinal nerves named here are illustrated, and most are also discussed, in chapter 13 (see tables 13.3 through 13.6).
- **Cranial nerves** arise from the base of the brain, emerge through the skull foramina, and innervate muscles of the head and neck. Cranial nerves are identified by roman numerals (CN I to CN XII) and by names given in table 14.1, although not all 12 of them innervate skeletal muscles.

The muscular system has a very heavy demand for energy, obtained from ATP, and thus it receives a generous flow of blood delivering oxygen and organic nutrients. Even at rest, it receives about one-quarter of all the blood pumped by the heart, or about 1.24 L/min. During exercise, its share may rise as high as three-quarters of the cardiac output, or about 11.6 L/min. Blood capillaries branch extensively through the endomysium to reach every muscle fiber, sometimes so intimately associated with the muscle fibers that the fibers have surface indentations to accommodate them. The capillaries of skeletal muscle undulate or coil when the muscle is contracted, allowing them enough slack to stretch out straight, without breaking, when the muscle lengthens. Chapter 20 describes some special physiological properties of muscle circulation and names the major arteries that supply the skeletal muscle groups.

10.1f Muscle Names and Learning Strategy

Figures 10.5 and 10.6 show an overview of the major superficial muscles. Learning the names of these and other muscles may seem a forbidding task at first, especially when some of them have such

¹²*syn* = together; *erg* = work

¹³*ant* = against; *agonist* = actor, competitor

FIGURE 10.5 The Muscular System, Anterior View. Major superficial muscles are shown on the anatomical right and some of the deeper muscles on the left. Muscles not labeled here are shown in more detail in later figures.

FIGURE 10.6 The Muscular System, Posterior View. Major superficial muscles are shown on the right and some of the deeper muscles on the left. Muscles not labeled here are shown in more detail in later figures.

long Latin names as *depressor labii inferioris* and *flexor digiti minimi brevis*. Such names, however, typically describe some distinctive aspects of the structure, location, or action of a muscle, and become very helpful once we grow familiar with a few common Latin words. For example, the *depressor labii inferioris* is a muscle that lowers (depresses) the bottom (inferior) lip (labium), and the *flexor digiti minimi brevis* is a short (*brevis*) muscle that flexes the smallest (*minimi*) finger (*digit*). Muscle names are interpreted in footnotes throughout the chapter. Familiarity with these terms and attention to the footnotes will help you translate muscle names and remember the location, appearance, and action of the muscles.

In the remainder of this chapter, we consider about 160 muscles; most courses cover considerably fewer according to the choices of individual instructors. The following suggestions may help you develop a rational strategy for learning the muscular system:

- Examine models, cadavers, dissected animals, or a photographic atlas as you read about these muscles. Visual images are often easier to remember than words, and direct observation of a muscle may stick in your memory better than descriptive text or two-dimensional drawings.
- When studying a particular muscle, palpate it on yourself if possible. Contract the muscle to feel it bulge and sense its action. This makes muscle locations and actions less abstract. Atlas B, following this chapter, shows where you can see and palpate several of these muscles on the living body.
- Locate the attachments of muscles on an articulated skeleton. Some skeletons and models are painted and labeled to show these. This helps you visualize the locations of muscles and understand how they produce particular joint actions.
- Study the derivation of each muscle name; the name usually describes the muscle's location, appearance, attachments, or actions.
- Say the names aloud to yourself or a study partner. It is harder to remember and spell terms you can't pronounce, and silent pronunciation isn't nearly as effective as speaking and hearing the names. Pronunciation guides based on the leading medical dictionaries are provided in the following muscle tables for all but the most obvious cases.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. List some functions of the muscular system other than movement of the body.
2. Describe the relationship of endomysium, perimysium, and epimysium to each other. Which of these separates one fascicle from another? Which separates one muscle from another?
3. Distinguish between direct and indirect muscle attachments to bones.
4. Define *belly*, *action*, and *innervation*.
5. Describe the five basic muscle shapes (fascicle arrangements).
6. Distinguish between a synergist, antagonist, and fixator. Explain how each of these may affect the action of a prime mover.

10.2 Muscles of the Head and Neck

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name and locate the muscles that produce facial expressions;
- b. name and locate the muscles used for chewing and swallowing;
- c. name and locate the neck muscles that move the head; and
- d. identify the attachments, actions, and innervation of these muscles.

The rest of this chapter consists largely of tables of the body's principal skeletal muscles. You will find a description and illustrations of each muscle group, with some generalizations and special-interest points about the group, then a table that gives the details:

- the name of each muscle in that group;
- the pronunciation of the name, unless it is self-evident or repeats words whose pronunciation has been provided in a recent entry;
- the actions of the muscle;
- the muscle's bony or soft-tissue attachments; and
- the nerve supply to that muscle.

We begin our survey of the muscular system with the head and neck (**fig. 10.7**). The first three sections divide these into muscles of facial expression, muscles of chewing and swallowing, and muscles that move the head as a whole.

FIGURE 10.7 Some Facial Muscles of the Cadaver. Boldface labels indicate muscles employed in facial expression.

Rebecca Gray/McGraw Hill

10.2a Muscles of Facial Expression

Humans have much more expressive faces than other mammals because of a complex array of muscles that insert in the dermis and subcutaneous tissues. These muscles tense the skin and produce such expressions as a pleasant smile, a flirtatious wink, a puzzled frown, or a threatening scowl (fig. 10.8). They add subtle shades of meaning to our spoken words. Facial muscles also contribute directly to speech, chewing, and other oral functions. All but one of them are innervated by the facial nerve (cranial nerve VII). This nerve is especially vulnerable to injury from lacerations and skull fractures, which can paralyze the muscles and cause parts of the face to sag. The only muscle not innervated by CN VII is the levator palpebrae superioris of the upper eyelid, innervated by the oculomotor nerve (CN III).

Table 10.1 groups these muscles into the following regions: the scalp; orbital and nasal regions (eye and nose); the oral region (encircling the mouth); and mental and buccal regions (chin and cheeks).

The Scalp

The **occipitofrontalis muscle** overlies the dome of the cranium. It is divided into a *frontal belly* in the forehead and *occipital belly* at the rear of the head (fig. 10.9), named for the underlying cranial bones. They are connected to each other by a broad aponeurosis, the **galea aponeurotica**¹⁴ (GAY-lee-uh AP-oh-new-ROT-ih-cuh).

The Orbital and Nasal Regions

The **orbicularis oculi** is a sphincter of the eyelid that encircles and closes the eye. Deep to it, in the eyelid and orbit, is the **levator palpebrae superioris**, which opens the eye. Other muscles in this group move the eyelids and skin of the forehead and dilate the nostrils. Muscles within the orbit that move the eyeball itself are discussed in relation to vision in chapter 16.

¹⁴*galea* = helmet; *apo* = above; *neuro* = nervous system, brain

FIGURE 10.8 Expressions Produced by Several of the Facial Muscles. The ordinary actions of these muscles are usually more subtle than these demonstrations.

? Name an antagonist of each of these muscles: the depressor anguli oris, orbicularis oculi, and levator labii superioris.

all: Joe DeGrandis/Ken Saladin

FIGURE 10.9 Muscles of Facial Expression.

(a) Anterior view. (b) Lateral view. Boldface labels indicate muscles employed in facial expression. **APR**

The Oral Region

The mouth is the most expressive part of the face, and lip movements are necessary for intelligible speech; thus, it's not surprising that the muscles here are especially diverse. The **orbicularis oris** is a complex of muscles in the lips that encircles the mouth; until recently it was misinterpreted as a sphincter, or circular muscle, but it is actually composed of four independent quadrants that interlace and give only an appearance of circularity. Other muscles in this region approach the lips from all directions and thus draw the lips or angles (corners) of the mouth upward, laterally, and downward. Some of these arise from a complex cord called the **modiolus**¹⁵ just lateral to each angle of the lips (fig. 10.9b). Named for the hub of a cartwheel, the modiolus is a point of convergence of several muscles of the lower face. You can palpate it by inserting one finger just inside the corner of your lips and pinching the corner between the finger and thumb, feeling for a thick knot of tissue.

The Mental and Buccal Regions

Adjacent to the oral orifice are the *mental region* (chin) and *buccal region* (cheek). In addition to muscles already discussed that act on the lower lip, the mental region has a pair of small **mentalis muscles** extending from the upper margin of the mandible to the skin of the chin. In some people, they are especially thick and have a visible dimple between them called the *mental cleft*. The **buccinator** is the muscle of the cheek. It has multiple functions in chewing, sucking, and blowing. If the cheeks are inflated with air, compression of the buccinators blows it out. Sucking is achieved by contracting the buccinators to draw the cheeks inward, then relaxing them. This action is especially important in nursing infants. To feel this action, hold your fingertips lightly against your cheeks as you make a kissing noise. You will notice motion of the buccinators at the moment air is sharply drawn in through the pursed lips. The **platysma** is a thin superficial muscle of the upper chest and lower face. It is relatively unimportant, but may help in depressing the mandible to open the mouth. It also draws the corners of the mouth down in expressions of extreme surprise or horror.

TABLE 10.1 Muscles of Facial Expression

Name	Action	Skeletal Attachments	Innervation
The Scalp			
Occipitofrontalis, frontal belly (oc-SIP-ih-toe-frun-TAY-lis)	Elevates eyebrows in glancing upward and expressions of surprise or fright; draws scalp forward and wrinkles skin of forehead	• Galea aponeurotica • Subcutaneous tissue of eyebrows	Facial nerve
Occipitofrontalis, occipital belly	Retracts scalp; fixes galea aponeurotica so frontal belly can act on eyebrows	• Superior nuchal line and temporal bone • Galea aponeurotica	Facial nerve
The Orbital and Nasal Regions			
Orbicularis oculi ¹⁶ (or-BIC-you-LERR-is OC-you-lye)	Sphincter of the eyelids; closes eye in blinking, squinting, and sleep; aids in flow of tears across eye	• Lacrimal bone; adjacent regions of frontal bone and maxilla; medial angle of eyelids • Upper and lower eyelids; skin around margin of orbit	Facial nerve
Levator palpebrae superioris ¹⁷ (leh-VAY-tur pal-PEE-bree soo-PEER-ee-OR-is)	Elevates upper eyelid; opens eye	• Lesser wing of sphenoid in posterior wall of orbit • Upper eyelid	Oculomotor nerve
Corrugator supercilii ¹⁸ (COR-oo-GAY-tur SOO-per-SIL-ee-eye)	Draws eyebrows medially and downward in frowning and concentration; reduces glare of bright sunlight	• Medial end of supraorbital margin • Skin of eyebrow	Facial nerve
Nasalis ¹⁹ (nay-ZAY-lis)	Widens nostrils; narrows internal air passage between vestibule and nasal cavity	• Maxilla just lateral to nose • Bridge and alar cartilages of nose	Facial nerve
The Oral Region			
Orbicularis oris ²⁰ (or-BIC-you-LERR-is OR-is)	Encircles mouth, closes lips, protrudes lips as in kissing; uniquely developed in humans for speech	• Modiolus of mouth • Submucosa and dermis of lips	Facial nerve

(continued)

¹⁵modiolus = hub

¹⁶orb = circle; ocul = eye

¹⁷levator = that which raises; palpebr = eyelid; superior = upper

¹⁸corrug = wrinkle; supercilii = of the eyebrow

¹⁹nas = of the nose

²⁰orb = circle; oris = of the mouth

TABLE 10.1 Muscles of Facial Expression (continued)			
Name	Action	Skeletal Attachments	Innervation
The Oral Region (continued)			
Levator labii superioris ²¹ (leh-VAY-tur LAY-bee-eye soo-PEER-ee-OR-is)	Elevates and everts upper lip in sad, sneering, or serious expressions	• Zygomatic bone and maxilla near inferior margin of orbit • Muscles of upper lip	Facial nerve
Levator anguli oris ²² (leh-VAY-tur ANG-you-lye OR-is)	Elevates angle of mouth as in smiling	• Maxilla just below infraorbital foramen • Muscles at angle of mouth	Facial nerve
Zygomaticus ²³ major (ZY-go-MAT-ih-cus)	Draws angle of mouth upward and laterally in laughing	• Zygomatic bone • Superolateral angle of mouth	Facial nerve
Zygomaticus minor	Elevates upper lip; exposes upper teeth in smiling or sneering	• Zygomatic bone • Muscles of upper lip	Facial nerve
Risorius ²⁴ (rih-SOR-ee-us)	Draws angle of mouth laterally in expressions of laughing, horror, or disdain	• Zygomatic arch; fascia near ear • Modiolus	Facial nerve
Depressor anguli oris ²⁵	Draws angle of mouth laterally and downward in opening mouth or sad expressions	• Inferior margin of mandibular body • Modiolus	Facial nerve
Depressor labii inferioris ²⁶	Draws lower lip downward and laterally in chewing and expressions of melancholy or doubt	• Mandible near mental protuberance • Skin and mucosa of lower lip	Facial nerve
The Mental and Buccal Regions			
Mentalis (men-TAY-lis)	Elevates and protrudes lower lip in drinking, pouting, and expressions of doubt or disdain; elevates and wrinkles skin of chin	• Mandible near inferior incisors • Skin of chin at mental protuberance	Facial nerve
Buccinator ²⁷ (BUC-sin-AY-tur)	Compresses cheek against teeth and gums; directs food between molars; retracts cheek from teeth when mouth is closing to prevent biting cheek; expels air and liquid from the mouth	• Alveolar processes on lateral surfaces of mandible and maxilla • Orbicularis oris; submucosa of cheek and lips	Facial nerve
Platysma ²⁸ (plah-TIZ-muh)	Draws lower lip and angle of mouth downward in expressions of horror or surprise; may aid in opening mouth widely; tenses skin of the chin and neck	• Fascia of deltoid and pectoralis major • Mandible; skin and subcutaneous tissue of lower face	Facial nerve

10.2b Muscles of Chewing and Swallowing

The muscles in this section are concerned primarily with the manipulation of food, including tongue movements, chewing, and swallowing.

Muscles of the Tongue

The tongue is a very agile organ. It pushes food between the molars for chewing and later forces it into the pharynx for swallowing. It is also, of course, crucial to articulate speech. Both intrinsic and extrinsic muscles are responsible for its complex movements. The *intrinsic muscles* consist of a variable number of vertical fascicles that extend from the superior to the inferior side of the tongue, transverse fascicles that extend from left to right, and longitudinal fascicles that extend from front to rear (see figs. 10.1c, 25.5b).

Table 10.2 describes the *extrinsic muscles* that connect the tongue to other structures in the head (fig. 10.10).

Muscles of Chewing

Four pairs of muscles produce the biting and cutting movements of the mandible: the **temporalis**, **masseter**, and two pairs of **pterygoid muscles** (fig. 10.11). Their actions include depression of the mandible for opening the mouth to receive food, elevation for biting off a piece of food or crushing it between the teeth; protraction so the incisors meet in cutting off a piece of food; retraction to draw the lower incisors behind the upper ones and make the rear teeth (premolars and molars) meet; and lateral and medial excursion, the side-to-side movements that grind food between the rear teeth (see fig. 9.20).

²¹*levat* = to raise; *labi* = lip; *superior* = upper
²²*angul* = angle, corner; *oris* = of the mouth
²³*zygo* = join, unite (refers to zygomatic bone)
²⁴*risor* = laughter

²⁵*depress* = to lower; *angul* = angle, corner; *oris* = of the mouth
²⁶*labi* = lip; *inferior* = lower
²⁷*buccinator* = trumpeter
²⁸*platy* = flat

FIGURE 10.10 Muscles of the Tongue and Pharynx.

FIGURE 10.11 Muscles of Chewing. Boldface labels indicate muscles that act on the mandible in its chewing movements. (a) Right lateral view. In order to expose the insertion of the temporalis muscle on the mandible, part of the zygomatic arch and masseter muscle are removed. (b) View of the pterygoid muscles looking into the oral cavity from behind the skull.

Suprahyoid Muscles

The hyoid bone, you will recall, is a slender U-shaped bone beneath the chin (see fig. 8.17). Eight pairs of *hyoid muscles* associated with this bone aid in chewing, swallowing, and speaking (**fig. 10.12**). Four of them, the *suprahyoid group*, are superior to the hyoid bone—the **digastric**, **geniohyoid**, **mylohyoid**, and

stylohyoid. The digastric is an unusual muscle named for its two bellies. Its *posterior belly* arises from the *mastoid notch* of the cranium and slopes downward and forward. The *anterior belly* arises from a trench called the *digastric fossa* on the inner surface of the mandibular body. It slopes downward and backward. The two bellies meet at a constriction, the *intermediate tendon*. This

FIGURE 10.12 Muscles of the Neck. (a) Anterior view. (b) Lateral view. Boldface labels indicate muscles of the suprahyoid and infrahyoid groups. Another muscle of the suprahyoid group, the geniohyoid, lies deep to the mylohyoid and can be seen in figure 10.10. **APR**

tendon passes through a connective tissue loop, the *fascial sling*, attached to the hyoid bone. Therefore, when the two bellies of the digastric contract, they elevate the hyoid; but if the hyoid is fixed from below, the digastric aids in wide opening of the mouth. The lateral pterygoids are more important in mouth opening, however, with the digastrics coming into play only in extreme opening, as in yawning or taking a large bite from an apple.

Infrahyoid Muscles

The *infrahyoid muscles* are inferior to the hyoid bone. By fixing the hyoid from below, they enable the suprahyoid muscles to open the mouth. The **omohyoid** is unusual in that it arises from

the shoulder, passes under the sternocleidomastoid muscle, then ascends to the hyoid bone. Like the digastric, it has two bellies—superior and inferior. The **thyrohyoid**, named for the hyoid bone and the large shield-shaped thyroid cartilage of the larynx, helps prevent choking. It elevates the larynx during swallowing so its superior opening is sealed by a flap of tissue, the epiglottis. You can feel this effect by holding a fingertip on your “Adam’s apple” (anterior prominence of the thyroid cartilage) and feeling it bob up as you swallow.

The infrahyoid muscles are also regarded as extrinsic muscles of the larynx, since they act on it from outside. The intrinsic muscles of the larynx are described in relation to breathing and speech in chapter 22. The *ansa cervicalis*²⁹ in table 10.2 is a loop

TABLE 10.2 Muscles of Chewing and Swallowing

Name	Action	Skeletal Attachments	Innervation
Extrinsic Muscles of the Tongue			
Genioglossus ³⁰ (JEE-nee-oh-GLOSS-us)	Unilateral action draws tongue to one side; bilateral action depresses midline of tongue or protrudes tongue	• Superior mental spine on posterior surface of mental protuberance • Inferior surface of tongue from root to apex	Hypoglossal nerve
Hyoglossus ³¹ (HI-oh-GLOSS-us)	Depresses tongue	• Body and greater horn of hyoid bone • Lateral and inferior surfaces of tongue	Hypoglossal nerve
Styloglossus ³² (STY-lo-GLOSS-us)	Draws tongue upward and posteriorly	• Styloid process of temporal bone and ligament from styloid process to mandible • Superolateral surface of tongue	Hypoglossal nerve
Palatoglossus ³³ (PAL-a-toe-GLOSS-us)	Elevates root of tongue and closes oral cavity off from pharynx; forms palatoglossal arch at rear of oral cavity	• Soft palate • Lateral surface of tongue	Accessory and vagus nerves
Muscles of Chewing			
Temporalis ³⁴ (TEM-po-RAY-liss)	Elevation, retraction, and lateral and medial excursion of the mandible	• Temporal lines and temporal fossa of cranium • Coronoid process and anterior border of mandibular ramus	Trigeminal nerve
Masseter ³⁵ (ma-SEE-tur)	Elevation of the mandible, with smaller roles in protraction, retraction, and lateral and medial excursion	• Zygomatic arch • Lateral surface of mandibular ramus and angle	Trigeminal nerve
Medial pterygoid ³⁶ (TERR-ih-goyd)	Elevation, protraction, and lateral and medial excursion of the mandible	• Medial surface of lateral pterygoid plate; palatine bone; lateral surface of maxilla near molar teeth • Medial surface of mandibular ramus and angle	Trigeminal nerve
Lateral pterygoid	Depression (in wide opening of the mouth), protraction, and lateral and medial excursion of the mandible	• Lateral surfaces of lateral pterygoid plate; greater wing of sphenoid • Neck of mandible (just below condyle); articular disc and capsule of temporomandibular joint	Trigeminal nerve

(continued)

²⁹*ansa* = handle; *cervic* = neck; *alis* = of, belonging to

³⁰*genio* = chin; *gloss* = tongue

³¹*hyo* = hyoid bone; *gloss* = tongue

³²*stylo* = styloid process; *gloss* = tongue

³³*palato* = palate; *gloss* = tongue

³⁴*temporalis* = of the temporal region of the head

³⁵*masset* = chew

³⁶*pteryg* = wing; *oid* = resembling (refers to pterygoid plate of sphenoid bone)

TABLE 10.2 Muscles of Chewing and Swallowing (continued)			
Name	Action	Skeletal Attachments	Innervation
Suprahyoid Muscles			
Digastric ³⁷	Depresses mandible when hyoid is fixed; opens mouth widely, as when ingesting food or yawning; elevates hyoid when mandible is fixed	• Mastoid notch of temporal bone; digastric fossa of mandible • Hyoid bone via fascial sling	Posterior belly: facial nerve Anterior belly: trigeminal nerve
Geniohyoid ³⁸ (JEE-nee-oh-HY-oyd)	Depresses mandible when hyoid is fixed; elevates and protracts hyoid when mandible is fixed	• Inferior mental spine of mandible • Hyoid bone	Spinal nerve C1 via hypoglossal nerve
Mylohyoid ³⁹	Spans mandible from side to side and forms floor of mouth; elevates floor of mouth in initial stage of swallowing	• Mylohyoid line near inferior margin • Hyoid bone	Trigeminal nerve
Stylohyoid	Elevates and retracts hyoid, elongating floor of mouth; roles in speech, chewing, and swallowing are not yet clearly understood	• Styloid process of temporal bone • Hyoid bone	Facial nerve
Infrahyoid Muscles			
Omohyoid ⁴⁰	Depresses hyoid after it has been elevated	• Superior border of scapula • Hyoid bone	Ansa cervicalis
Sternohyoid ⁴¹	Depresses hyoid after it has been elevated	• Manubrium of sternum; medial end of clavicle • Hyoid bone	Ansa cervicalis
Thyrohyoid ⁴²	Depresses hyoid; with hyoid fixed, elevates larynx as in singing high notes	• Thyroid cartilage of larynx • Hyoid bone	Spinal nerve C1 via hypoglossal nerve
Sternothyroid	Depresses larynx after it has been elevated in swallowing and vocalization; aids in singing low notes	• Manubrium of sternum; costal cartilage • Thyroid cartilage of larynx	Ansa cervicalis
Pharyngeal Muscles			
Superior, middle, and inferior pharyngeal constrictors	During swallowing, contract in order from <i>superior</i> to <i>middle</i> to <i>inferior constrictor</i> to drive food into esophagus	• Medial pterygoid plate; mandible; hyoid; stylohyoid ligament; cartilages of larynx • Posteromedial seam of pharynx; basilar part of occipital bone	Glossopharyngeal and vagus nerves

of nerve on the side of the neck that innervates three of the infrahyoid muscles; it is formed by certain nerve fibers from cervical nerves 1 to 3 (see fig. 13.15).

Pharyngeal Muscles

Three pairs of **pharyngeal constrictors** encircle the pharynx on its posterior and lateral sides, forming a muscular funnel (see fig. 10.10). In swallowing, they push food from the pharynx into the esophagus.

10.2c Muscles Acting on the Head and Neck

Muscles that move the head arise from the vertebral column, thoracic cage, and pectoral girdle and end on the cranial bones (**table 10.3**). Their actions include flexion (tipping the head forward), extension (holding the head erect), hyperextension (as in looking upward), lateral flexion (tilting the head to one side), and rotation (turning the head to look left or right). Flexion, extension, and hyperextension involve simultaneous action of the right and left muscles of a pair; the other actions require the muscle

³⁷*di* = two; *gastr* = bellies
³⁸*genio* = chin
³⁹*mylo* = mill, molar tooth

⁴⁰*omo* = shoulder
⁴¹*sterno* = chest, sternum
⁴²*thyro* = shield, thyroid cartilage

FIGURE 10.13 Muscles of the Shoulder and Nuchal Regions of the Cadaver.

Rebecca Gray/Don Kincaid/McGraw Hill

on one side to contract more strongly than its mate. Many head actions result from a combination of these movements—for example, looking up over the shoulder involves a combination of rotation and hyperextension.

Depending on its skeletal attachments, a muscle may cause a *contralateral* movement of the head (toward the opposite side, as when contraction of a muscle on the left turns the face toward the right) or an *ipsilateral* movement (toward the same side as the muscle, as when contraction of a muscle on the left tilts the head to the left).

Flexors of the Neck

The prime mover of neck flexion is the **sternocleidomastoid**, a thick muscular cord that extends from the upper chest (sternum and clavicle) to the mastoid process behind the ear (fig. 10.12). This is most easily seen when the head is rotated to one side and slightly extended. To visualize the action of a single sternocleidomastoid, place the index finger of your left hand on your left mastoid process and the index finger of your right hand on your suprasternal notch. Now contract your left sternocleidomastoid to bring your two fingertips as close together as possible. You will see that this tilts your face upward and to the right.

The three **scalenes**⁴³ on the side of the neck are named for their staircase-like arrangement. Their actions are similar so they are considered collectively in the table.

Extensors of the Neck

The extensors are located mainly in the nuchal region (back of the neck; fig. 10.13) and therefore tend to hold the head erect or draw it back. The **trapezius** is the largest and most superficial of these. It extends from the nuchal region over the shoulders and halfway down the back. It is named for the fact that the right and left trapezii together form a diamond or trapezoidal shape (see fig. 10.6). The *splenius* is a deeper, elongated muscle with **splenius capitis** and **splenius cervicis** regions in the head and neck, respectively. It is nicknamed the “bandage muscle” because of the way it wraps around still deeper neck muscles. One of those deeper muscles is the *semispinalis*, another elongated muscle with head, neck, and thoracic regions. Only the **semispinalis capitis** and **cervicis** are tabulated here; the *semispinalis thoracis* doesn’t act on the neck, but is included in table 10.6.

▶▶▶ APPLY WHAT YOU KNOW

Of the muscles you have studied so far, name three you would consider intrinsic muscles of the head and three you would classify as extrinsic. Explain your reason for each.

⁴³scal = staircase

TABLE 10.3 Muscles Acting on the Head and Neck

Name	Action	Skeletal Attachments	Innervation
Flexors of the Neck			
Sternocleidomastoid ⁴⁴ (STIR-no-CLY-do-MAST-oyd)	Unilateral action tilts head slightly upward and toward the opposite side, as in looking over one's contralateral shoulder. The most common action is probably rotating the head to the left or right. Bilateral action draws the head straight forward and down, as when eating or reading. Aids in deep breathing when head is fixed.	• Manubrium of sternum; medial one-third of clavicle • Mastoid process; lateral half of superior nuchal line	Accessory nerve; spinal nerves C2–C4
Anterior, middle, and posterior scalenes (SCAY-leens)	Unilateral contraction causes ipsilateral flexion or contralateral rotation (tilts head toward same shoulder, or rotates face away), depending on action of other muscles. Bilateral contraction flexes neck. If spine is fixed, scalenes elevate ribs 1–2 and aid in breathing.	• Transverse processes of all cervical vertebrae (C1–C7) • Ribs 1–2	Anterior rami of spinal nerves C3–C8
Extensors of the Neck			
Trapezius ⁴⁵ (tra-PEE-zee-us)	Extends and laterally flexes neck. See also roles in scapular movement in table 10.8.	• External occipital protuberance; medial one-third of superior nuchal line; nuchal ligament; spinous processes of vertebrae C7–T12 • Acromion and spine of scapula; lateral one-third of clavicle	Accessory nerve
Splenius capitis ⁴⁶ and splenius cervicis ⁴⁷ (SPLEE-nee-us CAP-ih-tiss, SIR-vih-sis)	Acting unilaterally, produce ipsilateral flexion and slight rotation of head; extend head when acting bilaterally	• Inferior half of nuchal ligament; spinous processes of vertebrae C7–T6 • Mastoid process and occipital bone just inferior to superior nuchal line; cervical vertebrae C1–C2 or C3	Posterior rami of middle cervical nerves
Semispinalis capitis and semispinalis cervicis (SEM-ee-spy-NAY-lis)	Extend and contralaterally rotate head	• Articular processes of vertebrae C4–C7; transverse processes of T1–T6 • Occipital bone between nuchal lines; spinous processes of vertebrae C2–C5	Posterior rami of cervical and thoracic nerves

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- Name two muscles that elevate the upper lip and two that depress the lower lip.
- Name the four paired muscles of mastication and state where they insert on the mandible.
- Distinguish between the functions of the suprahyoid and infrahyoid muscles.
- List the muscles of neck extension and flexion.

- name and locate the muscles of the abdominal wall, back, and pelvic floor; and
- identify the skeletal attachments, action, and innervation of these muscles.

10.3 Muscles of the Trunk**Expected Learning Outcomes**

When you have completed this section, you should be able to

- name and locate the muscles of respiration and explain how they affect airflow and abdominal pressure;

In this section, we will examine muscles of the trunk of the body in four functional groups concerned with respiration, support of the abdominal wall, movement of the vertebral column, and support of the pelvic floor. In the illustrations, you will note some major muscles that aren't discussed in the associated tables—for example, the pectoralis major and serratus anterior. Although they are *located* in the trunk, they *act upon* the limbs and limb girdles, and are further discussed in sections 10.4 and 10.5.

⁴⁴sterno = chest, sternum; *cleido* = hammer, clavicle; *masto* = breastlike, mastoid process

⁴⁵trapez = table, trapezoid

⁴⁶splenius = bandage; *capitis* = of the head

⁴⁷cervicis = of the neck

10.3a Muscles of Respiration

We breathe primarily by means of muscles that enclose the thoracic cavity—the diaphragm, external intercostal, internal intercostal, and innermost intercostal muscles (**fig. 10.14; table 10.4**).

The **diaphragm** is a muscular dome between the thoracic and abdominal cavities, bulging upward against the base of the lungs. It has openings for passage of the esophagus, major blood and lymphatic vessels, and nerves between the two cavities. Its fibers converge from the margins toward a fibrous **central tendon**. When the diaphragm contracts, it flattens slightly and enlarges the thoracic cavity, causing air intake (inspiration); when it relaxes, it rises and shrinks the thoracic cavity, expelling air (expiration).

Three layers of muscle lie between the ribs: the external, internal, and innermost intercostal muscles. The 11 pairs of **external intercostal muscles** constitute the most superficial layer. They extend from the rib tubercle posteriorly almost to the beginning of the costal cartilage anteriorly. Each one slopes downward and anteriorly from one rib to the next inferior one.

The 11 pairs of **internal intercostal muscles** lie deep to the external intercostals and extend from the margin of the sternum to the angles of the ribs. They are thickest in the region between the costal cartilages and grow thinner in the region where they overlap the external intercostals. Their fibers slope downward and posteriorly from each rib to the one below, at nearly right angles to the external intercostals. Each is divided into an *intercartilaginous part* between the costal cartilages and an *interosseous part* between the bony part of the ribs. The two parts differ in their respiratory roles.

The **innermost intercostal muscles** vary in number, as they are sometimes absent from the upper thoracic cage. Their fibers run in the same direction as the internal intercostals, and they are presumed to serve the same function. The internal and innermost intercostals are separated by a fascia that allows passage for intercostal nerves and blood vessels (see fig. 13.14b).

The primary function of the intercostal muscles is to stiffen the thoracic cage during respiration so it doesn't cave inward when the diaphragm descends. However, they also contribute to enlargement and contraction of the thoracic cage and thus add to the air volume that ventilates the lungs.

Many other muscles of the chest and abdomen contribute significantly to breathing: the sternocleidomastoid and scalenes of the neck; pectoralis major and serratus anterior of the chest; latissimus dorsi of the lower back; internal and external obliques and transverse abdominal muscle; and even some of the anal muscles. The respiratory actions of all these muscles are described in section 22.2a.

▶▶▶ APPLY WHAT YOU KNOW

A young thoracic surgery resident performing an operation for esophageal cancer accidentally severs the patient's left phrenic nerve. Predict the effect of this accident on the patient's respiration.

▶▶▶ APPLY WHAT YOU KNOW

Carl and Carla are enjoying a platter of barbecued ribs. What muscles are they eating? What is the tough fibrous membrane between the meat and the bone?

(a) Lateral view of intercostal muscles

(b) Inferior view of diaphragm

FIGURE 10.14 Muscles of Respiration. (a) Lateral view of the intercostal muscles. (b) Inferior view of the diaphragm. **APR**

TABLE 10.4 Muscles of Respiration			
Name	Action	Skeletal Attachments	Innervation
Diaphragm ⁴⁸ (DY-ah-fram)	Prime mover of inspiration (responsible for about two-thirds of air intake); contracts in preparation for sneezing, coughing, crying, laughing, and weight lifting; contraction compresses abdominal viscera and aids in childbirth and expulsion of urine and feces.	• Xiphoid process of sternum; ribs and costal cartilages 7–12; lumbar vertebrae • Central tendon of diaphragm	Phrenic nerves
External intercostals ⁴⁹ (IN-tur-COSS-tulz)	When scalenes fix rib 1, external intercostals elevate and protract ribs 2–12, expanding the thoracic cavity and creating a partial vacuum causing inflow of air; exercise a braking action during expiration so that expiration is not overly abrupt.	• Inferior margins of ribs 1–11 • Superior margin of next lower rib	Intercostal nerves
Internal intercostals	In inspiration, the intercartilaginous part aids in elevating the ribs and expanding the thoracic cavity; in expiration, the interosseous part depresses and retracts the ribs, compressing the thoracic cavity and expelling air; the latter occurs only in forceful expiration, not in relaxed breathing.	• Superior margins and costal cartilages of ribs 2–12; margin of sternum • Inferior margin of next higher rib	Intercostal nerves
Innermost intercostals	Presumed to have the same action as the internal intercostals	• Superomedial surface of ribs 2–12; may be absent from upper ribs • Medial edge of costal groove of next higher rib	Intercostal nerves

10.3b Muscles of the Abdominal Wall

Unlike the thoracic cavity, the abdominal cavity has little skeletal support. It is enclosed, however, in layers of broad flat muscles whose fibers run in different directions, strengthening the abdominal wall on the same principle as the alternating layers of wood fibers in plywood (table 10.5).

Three layers of muscle enclose the lumbar region and extend about halfway across the anterior abdomen (fig. 10.15). The most superficial layer is the **external oblique muscle**. Its fibers pass downward and anteriorly. The next deeper layer is the **internal oblique muscle**, whose fibers pass upward and anteriorly, roughly perpendicular to those of the external oblique. The deepest layer is the **transverse abdominal muscle (transversus abdominis)**, with horizontal fibers.

Anteriorly, a pair of vertical **rectus abdominis muscles** extends from sternum to pubis. These are divided into segments by three transverse *tendinous intersections*, giving them an appearance that body builders nickname the “six pack.”

The tendons of the oblique and transverse muscles are *aponeuroses*—broad fibrous sheets that continue medially and inferiorly (figs. 10.16, 10.17). At the rectus abdominis, they diverge and pass around its anterior and posterior sides, enclosing the muscle in a vertical sleeve called the rectus sheath. They meet again at a median line called the **linea alba**⁵⁰ between the rectus muscles. Another line, the **linea semilunaris**,⁵¹ marks the lateral boundary where the rectus sheath meets the aponeurosis. The aponeurosis of the external

Christine Eckel/McGraw Hill

TABLE 10.5 Muscles of the Abdominal Wall			
Name	Action	Skeletal Attachments	Innervation
External oblique	Supports abdominal viscera against pull of gravity; stabilizes vertebral column during heavy lifting; maintains posture; compresses abdominal organs, thus aiding in deep breathing, loud vocalizations such as singing and public speaking, and in expulsion of abdominopelvic contents during childbirth, urination, defecation, and vomiting; unilateral contraction causes contralateral rotation of the spine, as in twisting at the waist.	• Ribs 5–12 • Anterior half of iliac crest; symphysis and superior margin of pubis	Anterior rami of spinal nerves T7–T12
Internal oblique	Same as external oblique except that unilateral contraction causes ipsilateral rotation of waist	• Inguinal ligament; iliac crest; thoracolumbar fascia • Ribs 10–12; costal cartilages 7–10; pubis	Anterior rami of spinal nerves T7–L1
Transverse abdominal	Compresses abdominal contents, with same effects as external oblique, but does not contribute to movements of vertebral column	• Inguinal ligament; iliac crest; thoracolumbar fascia; costal cartilages 7–12 • Linea alba; pubis; aponeurosis of internal oblique	Anterior rami of spinal nerves T7–L1
Rectus ⁵² abdominis (REC-tus ab-DOM-ih-nis)	Flexes waist, as in bending forward or doing sit-ups; stabilizes pelvic region during walking; and compresses abdominal viscera	• Pubic symphysis and superior margin of pubis • Xiphoid process; costal cartilages 5–7	Anterior rami of spinal nerves T6–T12

⁵²rectus = straight

oblique also forms a cordlike **inguinal ligament** at its inferior margin. This extends obliquely from the anterior superior spine of the ilium to the pubis. The linea alba, linea semilunaris, and inguinal ligament are externally visible on a person with good muscle definition (see atlas B, fig. B.8). Weak points in the abdominal wall can be sites of inguinal and umbilical hernias (see Deeper Insight 10.3).

▶▶▶ APPLY WHAT YOU KNOW

Alice works out at a fitness center three times a week doing weight lifting and abdominal crunches. Martha prefers to sit on the sofa eating potato chips and watching

TV. Both become pregnant. Other things being equal, give one reason related to table 10.5 why Alice may have an easier time with her childbirth than Martha will.

10.3c Muscles of the Back

Muscles of the back (table 10.6) primarily extend, rotate, and laterally flex the vertebral column. The most prominent superficial back muscles are the *latissimus dorsi* and *trapezius* (fig. 10.18), but they are concerned with upper limb movements and covered in tables 10.8 and 10.9. Deep to these are the **serratus posterior superior** and **inferior** (figs. 10.18, 10.19). They extend from the

FIGURE 10.18 Neck, Back, and Gluteal Muscles. The most superficial muscles are shown on the left and the next deeper layer on the right. **APR**

FIGURE 10.19 Muscles Acting on the Vertebral Column. These are deeper than the muscles in figure 10.18, and those on the right are deeper than those on the left.

vertebrae to the ribs. They aid in deep breathing and are further discussed in chapter 22.

Deep to these is a prominent muscle, the **erector spinae**, which runs vertically for the entire length of the back from the cranium to the sacrum (**fig. 10.20**). It is a thick muscle on each side of the vertebral column in the lumbar region. (Pork chops and T-bone steaks are cut from the erector spinae muscles of animals.) As it ascends, it divides in the upper lumbar region into three parallel columns. The most lateral of these is the **iliocostalis**, which from inferior to superior is divided into the *iliocostalis lumborum*, *iliocostalis thoracis*, and *iliocostalis cervicis* (lumbar, thoracic, and cervical regions).

The next column medially is the **longissimus**, divided from inferior to superior into the *longissimus thoracis*, *longissimus cervicis*, and *longissimus capitis* (thoracic, cervical, and cephalic regions). The most medial column is the **spinalis**, divided into *spinalis thoracis*, *spinalis cervicis*, and *spinalis capitis*. The functions of all three columns are sufficiently similar that we will treat them collectively as the erector spinae.

The major deep muscles are the **semispinalis thoracis** in the thoracic region and **quadratus lumborum** in the lumbar region (**fig. 10.19**). The erector spinae and quadratus lumborum are enclosed in a fibrous sheath called the **thoracolumbar fascia** (**fig. 10.18**), which is the origin of some of the abdominal and

FIGURE 10.20 Deep Back Muscles of the Cadaver.

Rebecca Gray/Don Kincaid/McGraw Hill

TABLE 10.6

Muscles of the Back

Name	Action	Skeletal Attachments	Innervation
Erector spinae (eh-REC-tur SPY-nee)	Aids in sitting and standing erect; straightens back after one bends at waist, and is employed in arching the back; unilateral contraction flexes waist laterally; the longissimus capitis also produces ipsilateral rotation of the head.	• Nuchal ligament; ribs 3–12; thoracic and lumbar vertebrae; median and lateral sacral crests; thoracolumbar fascia • Mastoid process; cervical and thoracic vertebrae; all ribs	Posterior rami of cervical to lumbar spinal nerves
Semispinalis thoracis (SEM-ee-spy-NAY-liss tho-RA-sis)	Extension and contralateral rotation of vertebral column	• Vertebrae T6–T10 • Vertebrae C6–T4	Posterior rami of cervical and thoracic spinal nerves
Quadratus lumborum ⁵³ (quad-RAY-tus lum-BORE-um)	Unilateral contraction causes ipsilateral flexion of lumbar spine; bilateral contraction extends lumbar spine. Aids respiration by fixing rib 12 and stabilizing attachments of diaphragm.	• Iliac crest; iliolumbar ligament • Rib 12; vertebrae L1–L4	Anterior rami of spinal nerves T12–L4
Multifidus ⁵⁴ (mul-TIFF-ih-dus)	Stabilizes adjacent vertebrae, maintains posture, controls vertebral movement when erector spinae acts on spine	• Vertebrae C4–L5; posterior superior iliac spine; sacrum; aponeurosis of erector spinae • Laminae and spinous processes of vertebrae superior to origins	Posterior rami of cervical to lumbar spinal nerves

⁵³*quadrat* = four-sided; *lumborum* = of the lumbar region

⁵⁴*multi* = many; *fid* = branched, sectioned

DEEPER INSIGHT 10.2

CLINICAL APPLICATION

Heavy Lifting and Back Injuries

When you are fully bent over forward, as in touching your toes, the erector spinae is fully stretched. Because of the *length–tension relationship* explained in section 11.4e, muscles that are stretched to such extremes cannot contract very effectively. Standing up from such a position is therefore initiated by the hamstring muscles on the back of the thigh and the gluteus maximus of the buttocks. The erector spinae joins in the action when it is partially contracted.

Standing too suddenly or improperly lifting a heavy weight, however, can strain the erector spinae, cause painful muscle spasms, tear tendons and ligaments of the lower back, and rupture intervertebral discs. The lumbar muscles are adapted for maintaining posture, not for lifting. This is why it is important, in heavy lifting, to crouch and use the powerful extensor muscles of the thighs and buttocks to lift the load.

lumbar muscles. The **multifidus** is a collective name for a series of tiny muscles that connect adjacent vertebrae to each other from the cervical to lumbar region.

10.3d Muscles of the Pelvic Floor

The floor of the pelvic cavity (**fig. 10.21; table 10.7**) is a strong multilayered muscular sheet important for the support of the abdominal and pelvic viscera—especially in light of the bipedal stance of humans, since the abdominal wall no longer forms a supportive floor as it does in quadrupedal mammals. Weakness in the pelvic floor can result in urinary or fecal incontinence or the prolapse (dropping) of internal organs between the thighs. The muscles and skeletal landmarks here are also of special importance in obstetrics.

Viewed from within the pelvic cavity, its floor is formed mainly by an extensive muscle called the *levator ani*. Inferior to

FIGURE 10.21 Muscles of the Pelvic Floor. (a) The superficial perineal space, male, viewed from below (the inferior aspect). (b) The deep perineal space, female, viewed from the same perspective. Other than the vaginal canal, the sexes are nearly identical at this level, including the urogenital and anal triangles. The root of the penis does not extend to this level. (c) The pelvic diaphragm, female, viewed from above (from within the pelvic cavity).

TABLE 10.7 Muscles of the Pelvic Floor

Name	Action	Skeletal Attachments	Innervation
Superficial Perineal Space			
Ischiocavernosus ⁵⁵ (ISS-kee-oh-CAV-er-NO-sus)	Maintains erection of the penis or clitoris by compressing deep structures of the organ and forcing blood forward into its body	• Ramus and tuberosity of ischium • Ensheaths internal structures of penis and clitoris	Pudendal nerve
Bulbospongiosus ⁵⁶ (BUL-bo-SPUN-jee-OH-sus)	Expels residual urine from urethra after bladder has emptied. Aids in erection of penis or clitoris. In male, spasmodic contractions expel semen during ejaculation. In female, contractions constrict vaginal orifice and expel secretions of greater vestibular glands.	• Perineal body and median raphe • Male: ensheathes root of penis - Female: pubic symphysis	Pudendal nerve
Deep Perineal Space			
Deep transverse perineal	Anchors perineal body, which supports other pelvic muscles; supports vaginal and urethral canals	• Ischiopubic rami • Perineal body	Pudendal nerve
Compressor urethrae (yu-REE-three)	Aids in urine retention; found in females only	• Ischiopubic rami • Right and left compressor urethrae meet each other inferior to external urethral sphincter	Pudendal nerve; spinal nerves S2–S4; pelvic splanchnic nerve
Anal Triangle			
External anal sphincter	Retains feces in rectum until voluntarily voided	• Coccyx, perineal body • Encircles anal canal and orifice	Pudendal nerve; spinal nerves S2–S4; pelvic splanchnic nerve
Pelvic Diaphragm			
Levator ani ⁵⁷ (leh-VAY-tur AY-nye)	Compresses anal canal and reinforces external anal and urethral sphincters; supports uterus and other pelvic viscera; aids in falling away of the feces; vertical movements affect pressure differences between abdominal and thoracic cavities and thus aid in deep breathing.	• Inner surface of lesser pelvis from pubis through margin of obturator internus to spine of ischium • Coccyx via anococcygeal body; walls of urethra, vagina, and anal canal	Pudendal nerve; spinal nerves S2–S3

this is the **perineum** (PERR-ih-NEE-um), a diamond-shaped area between the thighs bordered by four bony landmarks: the pubic symphysis anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally. The pelvic floor and perineum are penetrated by the anal canal, urethra, and vagina. The anterior half of the perineum is the **urogenital triangle** and the posterior half is the **anal triangle**.

The urogenital triangle is divided into two muscle compartments separated by a strong fibrous **perineal membrane**. The muscle compartment between this membrane and the skin is called the *superficial perineal space*, and the compartment between the perineal membrane and levator ani is the *deep perineal space*. We will examine these structures beginning inferiorly, just beneath the skin, and progressing superiorly to the pelvic floor.

The Superficial Perineal Space

The **superficial perineal space** (fig. 10.21a) contains three pairs of muscles: the *ischiocavernosus*, *bulbospongiosus*, and

superficial transverse perineal muscles. In females, this space also contains the clitoris; various glands and erectile tissues of the genitalia (see fig. 28.8); and adipose tissue, which extends into and fattens the mons pubis and labia majora. In males, it contains the root of the penis.

The **ischiocavernosus muscles** converge like a V from the ischial tuberosities toward the penis or clitoris. In males, the **bulbospongiosus (bulbocavernosus) muscles** form a sheath around the root of the penis, and in females they enclose the vagina like a pair of parentheses. *Cavernosus* in these names refers to the spongy, cavernous structure of tissues in the penis and clitoris.

The **superficial transverse perineal muscles** extend from the ischial tuberosities to a strong median fibromuscular anchorage, the **perineal body**, and a median seam called the **perineal raphe** (RAY-fee) that extends anteriorly from the perineal body. These muscles may help to anchor the perineal body, but they are weakly developed and not always present, therefore not included in table 10.7. The other two muscle pairs of this layer serve primarily sexual functions.

⁵⁵*ischio* = ischium of hip bone; *cavernosus* = corpus cavernosum of the penis or clitoris

⁵⁶*bulbo* = bulb of the penis; *spongiosus* = corpus spongiosum of the penis

⁵⁷*levator* = that which elevates; *ani* = of the anus

DEEPER INSIGHT 10.3

CLINICAL APPLICATION

Hernias

A **hernia** is any condition in which the viscera protrude through a weak point in the muscular wall of the abdominopelvic cavity. The most common type to require treatment is an *inguinal hernia* (fig. 10.22). In the male fetus, each testis descends from the pelvic cavity into the scrotum by way of a passage called the *inguinal canal* through the muscles of the groin. A long pouch of peritoneum descends with the testis, but usually disappears by birth. Hernias occur in infants and children when this pouch persists, allowing a loop of intestine to enter it and appear near or in the scrotum (*indirect hernia*). Adult hernias may appear similar but are often due to a weakening of the inguinal canal (*direct hernia*). This can result from repetitive stress such as lifting weights. When the diaphragm and abdominal muscles contract, pressure in the abdominal cavity can soar to 1,500 pounds per square inch—more than 100 times the normal pressure and quite sufficient to produce an inguinal hernia, or “rupture.” Inguinal hernias in women occur through the pelvic floor and other nearby sites.

Two other sites of hernia are the diaphragm and navel. A *hiatal hernia* is a condition in which part of the stomach protrudes through the diaphragm into the thoracic cavity. This is most common in overweight people over 40. It may cause heartburn due to the regurgitation of stomach acid into the esophagus, but most cases go undetected. In an *umbilical hernia*, abdominal viscera protrude through the navel.

FIGURE 10.22 Inguinal Hernia. A loop of small intestine has protruded through the inguinal canal into a space beneath the skin.

The Deep Perineal Space

The **deep perineal space** (fig. 10.21b) contains a pair of **deep transverse perineal muscles** and, in females only, the **compressor urethrae muscles**. The deep transverse perineal muscles anchor the perineal body on the median plane; the perineal body, in turn, anchors other pelvic muscles. The female external urethral sphincter, long thought to be part of the deep perineal space, is now regarded as part of the urethra itself and not part of the pelvic floor musculature.

The Anal Triangle

The **anal triangle** contains the **external anal sphincter** and **anococcygeal ligament** (fig. 10.21b). The external anal sphincter is a tubular muscle surrounding the lower anal canal. The anococcygeal ligament is the median insertion of the levator ani muscles, and the ligament, in turn, inserts on the coccyx. It is therefore a major anchorage for the structures that compose the pelvic floor.

The Pelvic Diaphragm

The **pelvic diaphragm** (fig. 10.21c) is deep to the foregoing structures (uppermost in the pelvic floor) and is composed mainly

of the right and left **levator ani** muscles. (The piriformis, also illustrated, is primarily a lower limb muscle.) The levator ani spans most of the pelvic outlet and forms the floor of the lesser (true) pelvis. It is divided into three portions that are sometimes regarded as separate muscles—the *ischiococcygeus* (or *coccygeus*), *iliococcygeus*, and *pubococcygeus*. The left and right levator ani muscles converge on the anococcygeal ligament, through which they are indirectly anchored to the coccyx.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- Which muscles are used more often, the external intercostals or internal intercostals? Explain.
- Explain how pulmonary ventilation affects abdominal pressure and vice versa.
- Name a major superficial muscle and two major deep muscles of the back.
- Define *perineum*, *urogenital triangle*, and *anal triangle*.
- Name one muscle in the superficial perineal space, one in the urogenital diaphragm, and one in the pelvic diaphragm. State the function of each.

10.4 Muscles Acting on the Shoulder and Upper Limb

Expected Learning Outcomes

When you have completed this section, you should be able to

- name and locate the muscles that act on the pectoral girdle, shoulder, elbow, wrist, and hand;
- relate the actions of these muscles to the joint movements described in chapter 9; and
- describe the skeletal attachments, action, and innervation of these muscles.

The upper and lower limbs have numerous muscles that serve primarily for movement of the body and manipulation of objects. These muscles are organized into distinct compartments separated from each other by the interosseous membranes of the forearm and leg (see figs. 8.35, 8.41) and by intermuscular septa. In the ensuing tables, you will find muscles of the upper limb divided into anterior and posterior compartments, and those of

the lower limb divided into anterior, posterior, medial, and lateral compartments. In most limb regions, the muscle groups are further subdivided by thinner fasciae into superficial and deep layers.

The upper limb is used for a broad range of both powerful and subtle actions, ranging from climbing, grasping, and throwing to writing, playing musical instruments, and manipulating small objects. It therefore has an especially complex array of muscles, but the muscles fall into logical groups that make their functional relationships and names easier to understand. The next five tables group these into muscles that act on the scapula, those that act on the humerus and shoulder joint, those that act on the forearm and elbow joint, extrinsic (forearm) muscles that act on the wrist and hand, and intrinsic (hand) muscles that act on the fingers.

10.4a Muscles Acting on the Shoulder

Muscles that act on the pectoral girdle (**table 10.8**) extend from the axial skeleton to the clavicle and scapula. The scapula is only loosely attached to the thoracic cage and is capable of considerable movement (**fig. 10.23**)—rotation (as in raising and lowering the apex of the shoulder), elevation and depression (as in shrugging and lowering the shoulders), and

FIGURE 10.23 Actions of Some Thoracic Muscles on the Scapula. (a) Lateral and medial rotation. (b) Elevation and depression. (c) Retraction and protraction. Note that an individual muscle can contribute to multiple actions, depending on which fibers contract and what synergists act with it.

TABLE 10.8 Muscles Acting on the Shoulder			
Name	Action	Skeletal Attachments	Innervation
Anterior Group			
Pectoralis minor (PECK-toe-RAY-liss)	With serratus anterior, draws scapula laterally and forward around chest wall; with other muscles, rotates scapula and depresses apex of shoulder, as in reaching down to pick up a suitcase	• Ribs 3–5 and overlying fascia • Coracoid process of scapula	Medial and lateral pectoral nerves
Serratus ⁵⁸ anterior (serr-AY-tus)	With pectoralis minor, draws scapula laterally and forward around chest wall; protracts scapula, and is the prime mover in all forward-reaching and pushing actions; aids in rotating scapula to elevate apex of shoulder; fixes scapula during abduction of arm	• All or nearly all ribs • Medial border of scapula	Long thoracic nerve
Posterior Group			
Trapezius (tra-PEE-zee-us)	Stabilizes scapula and shoulder during arm movements; elevates and depresses apex of shoulder; acts with other muscles to rotate and retract scapula (see also roles in head and neck movements in table 10.3)	• External occipital protuberance; medial one-third of superior nuchal line; nuchal ligament; spinous processes of vertebrae C7–T12 • Acromion and spine of scapula; lateral one-third of clavicle	Accessory nerve
Levator scapulae (leh-VAY-tur SCAP-you-lee)	Elevates scapula if cervical vertebrae are fixed; flexes neck laterally if scapula is fixed; retracts scapula and braces shoulder; rotates scapula and depresses apex of shoulder	• Transverse processes of vertebrae C1–C4 • Superior angle to medial border of scapula	Spinal nerves C3–C4, and C5 via posterior scapular nerve
Rhomboid minor (ROM-boyd)	Retracts scapula and braces shoulder; fixes scapula during arm movements	• Spinous processes of vertebrae C7–T1; nuchal ligament • Medial border of scapula	Posterior scapular nerve
Rhomboid major	Same as rhomboid minor	• Spinous processes of vertebrae T2–T5 • Medial border of scapula	Posterior scapular nerve

protraction and retraction (pulling the shoulders forward and back). The clavicle braces the shoulder and moderates these movements.

Anterior Group

Muscles of the pectoral girdle fall into anterior and posterior groups (figs. 10.24, 10.25). The major muscles of the anterior group are the pectoralis minor and serratus anterior (see fig. 10.16b). The **pectoralis minor** arises by three heads from ribs 3 to 5 and converges on the coracoid process of the scapula. The **serratus anterior** is nicknamed the “boxer’s muscle” because of its role in powerful thrusting movements of the arm such as a boxer’s jab. It arises from separate heads on all or nearly all of the ribs, wraps laterally around the chest, passes across the back between the rib cage and scapula, and ends on the medial (vertebral) border of the scapula. Thus, when it contracts, the scapula glides laterally and slightly forward around the ribs.

FIGURE 10.24 Rotator Cuff Muscles in Relation to the Scapula (Lateral View). For posterior and anterior views of these muscles, see figure 10.25b and d.

(d) The brachialis, the deep flexor of the elbow, and the coracobrachialis and subscapularis, which act on the humerus. **APR**

Posterior Group

The posterior muscles that act on the scapula include the large, superficial **trapezius**, already discussed (see table 10.3), and three deep muscles: the **levator scapulae**, **rhomboid minor**, and **rhomboid major**. The action of the trapezius depends on whether its superior, middle, or inferior fibers contract and whether it acts alone or with other muscles. The levator scapulae and superior fibers of the trapezius rotate the scapula in opposite directions if either of them acts alone. If both act together, their opposite rotational effects balance each other and they elevate the scapula and shoulder, as when you lift a suitcase from the floor. Depression of the scapula occurs mainly by gravitational pull, but the trapezius and serratus anterior can depress it more rapidly and forcefully, as in swimming, hammering, and rowing.

10.4b Muscles Acting on the Arm

Nine muscles cross the shoulder joint and insert on the humerus (table 10.9). Seven of them are considered *scapular muscles* because they arise from the scapula, and the other two are considered *axial muscles* because they arise primarily from the axial skeleton.

Rotator Cuff Muscles

Tendons from four of the scapular muscles form the **rotator cuff** (fig. 10.24), well known as a common site of musculo-skeletal injury. These are nicknamed the “SITS muscles” for the first letters of their names—**supraspinatus**, **infraspinatus**, **teres minor**, and **subscapularis**. The first three of these lie on the posterior side of the scapula (fig. 10.25b). The supraspinatus and infraspinatus occupy the supraspinous and infraspinous fossae, above and below the scapular spine. The teres minor lies inferior to the infraspinatus. The subscapularis occupies the subscapular fossa on the anterior surface of the scapula, between the scapula and ribs (fig. 10.25d). The tendons of these muscles merge with the joint capsule of the shoulder as they cross it en route to the humerus. They insert on the proximal end of the humerus, forming a partial sleeve around it. The rotator cuff reinforces the joint capsule and holds the head of the humerus in the glenoid cavity. It is easily damaged by strenuous actions of the shoulder (see Deeper Insight 10.4).

Other Scapular Muscles

Of the remaining three scapular muscles, the most conspicuous is the **deltoid**, the thick triangular muscle that caps the shoulder (fig. 10.25a). Intramuscular drug injections are often given here. Its anterior, lateral, and posterior fibers act like three different

muscles. The **teres major** and **coracobrachialis** complete this group (fig. 10.25b, d).

Axial Muscles

The two axial muscles, both prominent, are the pectoralis major anteriorly and latissimus dorsi posteriorly (fig. 10.25a, b; fig. 10.26). The **pectoralis major** is the thick, fleshy muscle of the mammary region and the **latissimus dorsi** is a broad muscle of the back that extends from the waist to the axilla. These muscles bear the primary responsibility for attaching the arm to the trunk and are the prime movers of the shoulder joint.

10.4c Muscles Acting on the Elbow and Forearm

The elbow and forearm are capable of four motions—flexion, extension, pronation, and supination—carried out by muscles in both the brachium and antebrachium (arm and forearm) (table 10.10).

Muscles of the Brachial Region

The principal elbow flexors are in the anterior compartment of the arm—the **brachialis** and **biceps brachii** (fig. 10.25c, d). The biceps brachii appears as a large anterior bulge on the arm and commands considerable interest among body builders, but the brachialis underlying it generates about 50% more power and is thus the prime mover of elbow flexion. The biceps is not only a flexor but also a powerful forearm supinator. It is named for its two heads: a *short head* whose tendon arises from the coracoid process of the scapula, and a *long head* whose tendon arises from the superior margin of the glenoid cavity, loops over the shoulder, and braces the humerus against the glenoid cavity. The two heads converge close to the elbow on a single distal tendon that terminates on the radius and on the fascia of the medial side of the upper forearm. Note that *biceps* is the singular term; there is no muscle named the *bicep*.

The **triceps brachii** is a three-headed muscle on the posterior side of the humerus, and is the prime mover of elbow extension (fig. 10.25b).

Muscles of the Antebrachial Region

Most forearm muscles act on the wrist and hand, but two of them are synergists in elbow flexion and extension and three of them function in pronation and supination. The **brachioradialis** is the large fleshy mass of the lateral (radial) side of the forearm just distal to the elbow (fig. 10.25a; also see fig. 10.29a). It extends from the distal end of the humerus to

TABLE 10.9 Muscles Acting on the Arm

Name	Action	Skeletal Attachments	Innervation
Rotator Cuff Muscles			
Supraspinatus ⁵⁹ (SOO-pra-spy-NAY-tus)	Aids deltoid in abduction of arm; resists downward slippage of humeral head when arm is relaxed or when carrying weight	• Supraspinous fossa of scapula • Greater tubercle of humerus	Suprascapular nerve
Infraspinatus ⁶⁰ (IN-fra-spy-NAY-tus)	Modulates action of deltoid, preventing humeral head from sliding upward; rotates humerus laterally	• Infraspinous fossa of scapula • Greater tubercle of humerus	Suprascapular nerve
Teres minor (TERR-eez)	Modulates action of deltoid, preventing humeral head from sliding upward as arm is abducted; rotates humerus laterally	• Lateral border and adjacent posterior surface of scapula • Greater tubercle of humerus; posterior surface of joint capsule	Axillary nerve
Subscapularis ⁶¹ (SUB-SCAP-you-LERR-iss)	Modulates action of deltoid, preventing humeral head from sliding upward as arm is abducted; rotates humerus medially	• Subscapular fossa of scapula • Lesser tubercle of humerus; anterior surface of joint capsule	Upper and lower subscapular nerves
Other Scapular Muscles			
Deltoid	Anterior fibers flex and medially rotate arm; lateral fibers abduct arm; posterior fibers extend and laterally rotate arm; involved in arm swinging during such actions as walking or bowling, and in adjustment of hand height for various manual tasks	• Acromion and spine of scapula; clavicle • Deltoid tuberosity of humerus	Axillary nerve
Teres major (TERR-eez)	Extends and medially rotates humerus; contributes to arm swinging	• Inferior angle of scapula • Medial lip of intertubercular sulcus of humerus	Lower subscapular nerve
Coracobrachialis (COR-uh-co-BRAY-kee-AY-lis)	Flexes and medially rotates arm; resists deviation of arm from frontal plane during abduction	• Coracoid process • Medial aspect of humeral shaft	Musculocutaneous nerve
Axial Muscles			
Pectoralis major (PECK-toe-RAY-liss)	Flexes, adducts, and medially rotates humerus, as in climbing or hugging; aids in deep inspiration	• Medial half of clavicle; lateral margin of sternum; costal cartilages 1–7; aponeurosis of external oblique • Lateral lip of intertubercular sulcus of humerus	Medial and lateral pectoral nerves
Latissimus dorsi ⁶² (la-TISS-ih-mus DOR-sye)	Adducts and medially rotates humerus; extends the shoulder joint as in pulling on the oars of a rowboat; produces backward swing of arm in such actions as walking and bowling; with hands grasping overhead objects, pulls body forward and upward, as in climbing; aids in deep inspiration, sudden expiration such as sneezing and coughing, and prolonged forceful expiration as in singing or blowing a sustained note on a wind instrument	• Vertebrae T7–L5; lower three or four ribs; iliac crest; thoracolumbar fascia • Floor of intertubercular sulcus of humerus	Thoracodorsal nerve

▶▶▶ APPLY WHAT YOU KNOW

Perform an action as if lifting a cup to your mouth to take a sip of tea. Describe the contribution of your deltoid to this action, using the terminology of joint movement in section 9.2c.

⁵⁹*supra* = above; *spin* = spine of scapula

⁶⁰*infra* = below, under; *spin* = spine of scapula

⁶¹*sub* = below, under

⁶²*latissimus* = broadest; *dorsi* = of the back

DEEPER INSIGHT 10.4

CLINICAL APPLICATION

Rotator Cuff Injury

Rotator cuff injury is a tear in the tendon of any of the SITS (rotator cuff) muscles, most often the supraspinatus. Such injuries are caused by strenuous circumduction of the arm, shoulder dislocation, hard falls or blows to the shoulder, or repetitive use of the arm in a position above the horizontal. They are common among baseball pitchers and third basemen, bowlers, swimmers, and weight lifters, and in racquet sports. Recurrent inflammation of a SITS tendon can cause a tendon to degenerate and then to rupture in response to moderate stress. Injury causes pain and makes the shoulder joint unstable and subject to dislocation.

the distal end of the radius. With the latter attachment so far from the fulcrum of the elbow, it doesn't generate as much force as the brachialis and biceps; it is effective mainly when those muscles have already partially flexed the elbow. The **anconeus** is a weak synergist of elbow extension on the posterior side of the elbow (see fig. 10.30).

Pronation and supination are important forearm movements for such purposes as eating, manipulating and inspecting objects in the hands, and generating force in twisting movements of the hand (see fig. 9.18). The prime mover of pronation is the **pronator quadratus** near the wrist; the **pronator teres** near the elbow is a synergist. Supination is usually achieved by the **supinator** of the upper forearm, with the biceps brachii aiding when additional speed or power is required (fig. 10.27).

TABLE 10.10 Muscles Acting on the Elbow and Forearm

Name	Action	Skeletal Attachments	Innervation
Muscles of the Brachial Region			
Brachialis (BRAY-kee-AY-lis)	Prime mover of elbow flexion	• Anterior surface of distal half of humerus • Coronoid process and tuberosity of ulna	Musculocutaneous nerve; radial nerve
Biceps brachii (BY-seps BRAY-kee-eye)	Rapid or forceful supination of forearm; synergist in elbow flexion; slight shoulder flexion; tendon of long head stabilizes shoulder by holding humeral head against glenoid cavity	• Long head: superior margin of glenoid cavity • Short head: coracoid process • Tuberosity of radius; fascia of forearm	Musculocutaneous nerve
Triceps brachii (TRI-seps BRAY-kee-eye)	Extends elbow; long head extends and adducts humerus	• Long head: inferior margin of glenoid cavity and joint capsule • Lateral head: posterior surface of proximal end of humerus • Medial head: posterior surface of entire humeral shaft • Olecranon; fascia of forearm	Radial nerve
Muscles of the Antebrachial Region			
Brachioradialis (BRAY-kee-oh-RAY-dee-AY-lis)	Flexes elbow	• Lateral supracondylar ridge of humerus • Lateral surface of radius near styloid process	Radial nerve
Anconeus ⁶³ (an-CO-nee-us)	Extends elbow; may help to control ulnar movement during pronation	• Lateral epicondyle of humerus • Olecranon and posterior surface of ulna	Radial nerve
Pronator quadratus (PRO-nay-tur quad-RAY-tus)	Prime mover of forearm pronation; also resists separation of radius and ulna when force is applied to forearm through wrist, as in doing push-ups	• Anterior surface of distal ulna • Anterior surface of distal radius	Median nerve
Pronator teres (PRO-nay-tur TERR-eez)	Assists pronator quadratus in pronation, but only in rapid or forceful action; weakly flexes elbow	• Humeral shaft near medial epicondyle; coronoid process of ulna • Lateral surface of radial shaft	Median nerve
Supinator (SOO-pih-NAY-tur)	Supinates forearm	• Lateral epicondyle of humerus; supinator crest and fossa of ulna just distal to radial notch; anular and radial collateral ligaments of elbow • Proximal one-third of radius	Radial nerve

⁶³anconeus = elbow

FIGURE 10.27 Actions of the Rotator Muscles on the Left Forearm. (a) Pronation. (b) Supination. (c) Cross section just distal to the elbow showing the synergistic action of the biceps brachii and supinator when additional speed or power is needed. (The biceps is not shown in “a” or “b” because it would cover those muscles.)

? What do the names of the pronator teres and pronator quadratus muscles indicate about their shapes?

10.4d Muscles Acting on the Wrist and Hand

The hand is acted upon by extrinsic muscles in the forearm (**table 10.11**) and intrinsic muscles in the hand itself. The bellies of the extrinsic muscles, along with the brachioradialis, form the fleshy roundness of the upper forearm; their tendons extend into the wrist and hand. Their actions are mainly flexion and extension of the wrist and digits, but also include radial and ulnar flexion, finger abduction and adduction, and thumb opposition. These muscles are numerous and complex, but their names often describe their location, appearance, and function.

Many of them act on the **metacarpophalangeal joints** between the metacarpal bones of the hand and the proximal phalanges of the fingers, and the **interphalangeal joints** between the proximal and middle or the middle and distal phalanges of the fingers (or between the proximal and distal phalanges in the thumb, which has no middle phalanx). The metacarpophalangeal joints form the knuckles at the bases of the fingers,

and the interphalangeal joints form the second and third knuckles. Some tendons cross multiple joints before inserting on a middle or distal phalanx, and can flex or extend all the joints they cross.

Fasciae divide the forearm muscles into anterior and posterior compartments and each compartment into superficial and deep layers (**fig. 10.28**). The muscles in these four groups are described in the following sections.

The Anterior (Flexor) Compartment, Superficial Layer

Most muscles of the anterior compartment are wrist and finger flexors that arise from a common tendon on the humerus (**fig. 10.29**). The two prominent tendons you can palpate at the wrist belong to the **palmaris longus** on the medial side and the **flexor carpi radialis** on the lateral side (see **fig. B.19a**). The latter is an important landmark for finding the radial

FIGURE 10.28 Serial Cross Sections Through the Left Upper Limb. Each section is taken at the correspondingly lettered level in the figure at the left and is pictured with the posterior muscle compartment facing the bottom of the page, as if viewing a person's left limb extended away from you with the palm up. (a) Superior arm at axilla. (b) Inferior arm. (c) Superior forearm.

? Why are the *extensor pollicis longus* and *extensor indicis* not seen in part (c)?

FIGURE 10.29 Flexors of the Wrist and Hand. Anterior views of the right forearm. (a) Superficial flexors. (b) The intermediate flexor digitorum superficialis, deep to the muscles in part (a). (c) Deep flexors. Flexor muscles of each compartment are labeled in boldface. **APR**

artery, where the pulse is usually taken. The palmaris longus is absent on one or both sides (most commonly the left) in about 14% of people. To see if you have one, flex your wrist and touch the tips of your thumb and little finger together. If present, the palmaris longus tendon will stand up prominently on the wrist.

Most tendons of these flexor muscles pass under a fibrous, braceletlike ligament called the **flexor retinaculum** on the anterior side of the wrist; the palmaris longus tendon, unlike the rest, passes over it. The retinaculum prevents the tendons from standing up like taut bowstrings when the flexors contract. The **carpal tunnel** is a tight space between the flexor retinaculum and carpal bones. The flexor tendons passing through the tunnel are enclosed in tendon sheaths that enable them to slide back and forth quite easily, although continual repetitive motion of these tendons can cause the painful inflammation known as *carpal tunnel syndrome* (see Deeper Insight 10.5).

The Anterior (Flexor) Compartment, Deep Layer

Two anterior flexors constitute the deep layer—the **flexor digitorum profundus**, which flexes fingers II–V, and the **flexor pollicis longus**, which flexes only the thumb (fig. 10.29c). The latter is one of several muscles serving exclusively for the varied thumb movements such as flexion, extension, abduction, adduction, opposition, and reposition (see fig. 9.21).

The Posterior (Extensor) Compartment, Superficial Layer

Superficial muscles of the posterior compartment are mostly wrist and finger extensors, and share a single tendon arising from the humerus (fig. 10.30a). The first of these, the **extensor digitorum**, has four distal tendons that can easily be seen and palpated on the back of the hand when the fingers are strongly extended (see fig. B.19b). These tendons pass under an extensor retinaculum (see fig. 5.13) similar to the flexor retinaculum on the anterior side of the wrist. This muscle serves digits II through V, and the other muscles in this group each serve a single digit. These superficial extensors are tabulated in table 10.11 from lateral to medial.

The Posterior (Extensor) Compartment, Deep Layer

The deep muscles that follow serve only the thumb and index finger (fig. 10.30b). By strongly abducting and extending the thumb into a hitchhiker's position, you may see a deep dorsolateral pit at the base of the thumb, with a taut tendon on each side of it (see fig. B.19b). This depression is called the *anatomical snuffbox* because it was once fashionable to place a pinch of snuff here and inhale it. It is bordered laterally by the tendons of the **abductor pollicis longus** and **extensor pollicis brevis**, and medially by the tendon of the **extensor pollicis longus**. Dedication of so many muscles to the thumb alone (to which *pollicis* refers) attests to the supreme importance of the thumb for so much of the hand's functionality;

FIGURE 10.30 Extensors of the Wrist and Hand. Posterior views of the right forearm. Extensor muscles of each compartment are labeled in boldface. (a) Superficial extensors. (b) Deep extensors. **APR**

TABLE 10.11 Muscles Acting on the Wrist and Hand			
Name	Action	Skeletal Attachments	Innervation
The Anterior (Flexor) Compartment, Superficial Layer			
Flexor carpi radialis ⁶⁴ (FLEX-ur CAR-pye RAY-dee-AY-lis)	Flexes wrist anteriorly; aids in radial flexion of wrist	• Medial epicondyle of humerus • Base of metacarpals II–III	Median nerve
Flexor carpi ulnaris ⁶⁵ (ul-NAY-ris)	Flexes wrist anteriorly; aids in ulnar flexion of wrist	• Medial epicondyle of humerus; medial margin of olecranon; posterior surface of ulna • Metacarpal V; pisiform; hamate	Ulnar nerve
Flexor digitorum superficialis ⁶⁶ (DIDJ-ih-TOE-rum SOO-per-FISH-ee-AY-lis)	Flexes wrist, metacarpophalangeal, and interphalangeal joints depending on action of other muscles	• Medial epicondyle of humerus; ulnar collateral ligament; coronoid process; superior half of radius • Middle phalanges II–V	Median nerve
Palmaris longus (pal-MERR-iss)	Anchors skin and fascia of palmar region; resists shearing forces when stress is applied to skin by such actions as climbing and tool use. Weakly developed and sometimes absent.	• Medial epicondyle of humerus • Flexor retinaculum, palmar aponeurosis	Median nerve

(continued)

⁶⁴*carpi* = of the wrist; *radialis* = of the radius

⁶⁵*ulnaris* = of the ulna

⁶⁶*digitorum* = of the digits; *superficialis* = shallow, near the surface

TABLE 10.11 Muscles Acting on the Wrist and Hand (continued)			
Name	Action	Skeletal Attachments	Innervation
Anterior (Flexor) Compartment, Deep Layer			
Flexor digitorum profundus ⁶⁷	Flexes wrist, metacarpophalangeal, and interphalangeal joints; sole flexor of the distal interphalangeal joints	• Proximal three-quarters of ulna; coronoid process; interosseous membrane • Distal phalanges II–V	Median nerve; ulnar nerve
Flexor pollicis ⁶⁸ longus (PAHL-ih-sis)	Flexes phalanges of thumb	• Radius; interosseous membrane • Distal phalanx I	Median nerve
Posterior (Extensor) Compartment, Superficial Layer			
Extensor carpi radialis longus	Extends wrist; aids in radial flexion of wrist	• Lateral supracondylar ridge of humerus • Base of metacarpal II	Radial nerve
Extensor carpi radialis brevis (BREV-iss)	Extends wrist; aids in radial flexion of wrist	• Lateral epicondyle of humerus • Base of metacarpal III	Radial nerve
Extensor digitorum	Extends wrist, metacarpophalangeal, and interphalangeal joints; tends to spread digits apart when extending metacarpophalangeal joints	• Lateral epicondyle of humerus • Dorsal surfaces of phalanges II–V	Radial nerve
Extensor digiti minimi ⁶⁹ (DIDJ-ih-ty MIN-ih-my)	Extends wrist and all joints of little finger	• Lateral epicondyle of humerus • Proximal phalanx V	Radial nerve
Extensor carpi ulnaris	Extends and fixes wrist when fist is clenched or hand grips an object; aids in ulnar flexion of wrist	• Lateral epicondyle of humerus; posterior surface of ulnar shaft • Base of metacarpal V	Radial nerve
Posterior (Extensor) Compartment, Deep Layer			
Abductor pollicis longus	Abducts thumb in frontal (palmar) plane (radial abduction); extends thumb at carpometacarpal joint	• Posterior surfaces of radius and ulna; interosseous membrane • Trapezium; base of metacarpal I	Radial nerve
Extensor pollicis brevis	Extends metacarpal I and proximal phalanx of thumb	• Shaft of radius; interosseous membrane • Proximal phalanx I	Radial nerve
Extensor pollicis longus	Extends distal phalanx I; aids in extending proximal phalanx I and metacarpal I; adducts and laterally rotates thumb	• Posterior surface of ulna; interosseous membrane • Distal phalanx I	Radial nerve
Extensor indicis (IN-dih-sis)	Extends wrist and index finger	• Posterior surface of ulna; interosseous membrane • Middle and distal phalanges of index finger	Radial nerve

try to imagine how much less you could do with your hands without the thumbs and these muscles.

10.4e Intrinsic Muscles of the Hand

The intrinsic muscles of the hand (table 10.12) assist the flexors and extensors in the forearm and make finger movements more

precise. They are divided into three groups: the *thenar group* at the base of the thumb, the *hypothenar group* at the base of the little finger, and the *midpalmar group* between these (fig. 10.32).

The Thenar Group

The **thenar group** of muscles forms the thick fleshy mass (*thenar eminence*) at the base of the thumb, and the **adductor pollicis** forms the web between the thumb and palm. All are concerned with thumb movements. The adductor pollicis has an oblique head that extends from the capitate bone of the wrist to

⁶⁷*profundus* = deep
⁶⁸*pollicis* = of the thumb
⁶⁹*digit* = finger; *minim* = smallest

DEEPER INSIGHT 10.5

CLINICAL APPLICATION

Carpal Tunnel Syndrome

Prolonged, repetitive motions of the wrist and fingers can cause tissues in the carpal tunnel to become inflamed, swollen, or fibrotic. Since the carpal tunnel cannot expand, swelling puts pressure on the median nerve of the wrist, which passes through the carpal tunnel with the flexor tendons (**fig. 10.31**). This pressure causes tingling and muscular weakness in the palm and medial side of the hand and pain that may radiate

to the arm and shoulder. This condition, called **carpal tunnel syndrome**, is common among keyboard operators, pianists, meat cutters, and others who spend long hours making repetitive wrist motions. Carpal tunnel syndrome is treated with aspirin and other anti-inflammatory drugs, immobilization of the wrist, and sometimes dividing the flexor retinaculum with a longitudinal incision to relieve pressure on the nerve.

FIGURE 10.31 The Carpal Tunnel. (a) Dissection of the right wrist (anterior view) showing the tendons, nerve, and bursae that pass under the flexor retinaculum. **APR** (b) Cross section of the right wrist, viewed as if from the distal end of a person's forearm extended toward you with the palm up. Note how the flexor tendons and median nerve are confined in the tight space between the carpal bones and flexor retinaculum. That tight packing and repetitive sliding of the flexor tendons through the tunnel contribute to carpal tunnel syndrome.

TABLE 10.12 Intrinsic Muscles of the Hand

Name	Action	Skeletal Attachments	Innervation
Thenar Group			
Adductor pollicis	Draws thumb toward palm as in gripping a tool	• Capitate; bases of metacarpals II–III; anterior ligaments of wrist; tendon sheath of flexor carpi radialis • Medial surface of proximal phalanx I	Ulnar nerve
Abductor pollicis brevis	Abducts thumb in sagittal plane	• Mainly flexor retinaculum; also scaphoid, trapezium, and abductor pollicis longus tendon • Lateral surface of proximal phalanx I	Median nerve
Flexor pollicis brevis	Flexes metacarpophalangeal joint of thumb	• Trapezium; trapezoid; capitate; anterior ligaments of wrist; flexor retinaculum • Proximal phalanx I	Median nerve; ulnar nerve
Opponens pollicis (op-PO-nenz)	Flexes metacarpal I to oppose thumb to fingertips	• Trapezium; flexor retinaculum • Metacarpal I	Median nerve
Hypothenar Group			
Abductor digiti minimi	Abducts little finger, as in spreading fingers apart	• Pisiform; tendon of flexor carpi ulnaris • Medial surface of proximal phalanx V	Ulnar nerve
Flexor digiti minimi brevis	Flexes little finger at metacarpophalangeal joint	• Hamulus of hamate bone; flexor retinaculum • Medial surface of proximal phalanx V	Ulnar nerve
Opponens digiti minimi	Flexes metacarpal V at carpometacarpal joint when little finger is moved into opposition with tip of thumb; deepens palm of hand	• Hamulus of hamate bone; flexor retinaculum • Medial surface of metacarpal V	Ulnar nerve
Midpalmar Group			
Four dorsal interosseous ⁷⁰ muscles (IN-tur-OSS-ee-us)	Abduct fingers; strongly flex metacarpophalangeal joints but extend interphalangeal joints, depending on action of other muscles; important in grip strength	• Each with two heads arising from facing surfaces of adjacent metacarpals • Proximal phalanges II–IV	Ulnar nerve
Three palmar interosseous muscles	Adduct fingers; other actions same as for dorsal interosseous muscles	• Metacarpals I, II, IV, V • Proximal phalanges II, IV, V	Ulnar nerve
Four lumbrical ⁷¹ muscles (LUM-brih-cul)	Extend interphalangeal joints; contribute to ability to pinch objects between fleshy pulp of thumb and finger, instead of these digits meeting by the edges of their nails	• Tendons of flexor digitorum profundus • Proximal phalanges II–V	Median nerve; ulnar nerve

the ulnar side of the base of the thumb, and a transverse head that extends from metacarpal III to the same termination as the oblique head.

The Hypothenar Group

The **hypothenar group** forms the fleshy mass (*hypothenar eminence*) at the base of the little finger. All of these muscles are concerned with movement of that digit.

The Midpalmar Group

The **midpalmar group** occupies the hollow of the palm. It has 11 small muscles divided into three groups—four **dorsal interosseous**, three **palmar interosseous**, and four **lumbrical muscles**.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

16. Name a muscle that inserts on the scapula and plays a significant role in each of the following actions:
 - a. pushing a stalled car,
 - b. paddling a canoe,

⁷⁰inter = between; osse = bones

⁷¹lumbrical = resembling an earthworm

- c. squaring the shoulders in military attention,
 - d. lifting the shoulder to carry a heavy box on it, and
 - e. lowering the shoulder to lift a suitcase.
17. Describe three contrasting actions of the deltoid muscle.
 18. Name the four rotator cuff muscles and describe the scapular surfaces against which they lie.
 19. Name the prime movers of elbow flexion and extension.
 20. Identify three functions of the biceps brachii.
 21. Name three extrinsic muscles and two intrinsic muscles that flex the phalanges.

10.5 Muscles Acting on the Hip and Lower Limb

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name and locate the muscles that act on the hip, knee, ankle, and toe joints;
- b. relate the actions of these muscles to the joint movements described in chapter 9; and
- c. describe the skeletal attachments, action, and innervation of these muscles.

The largest muscles are found in the lower limb. Unlike those of the upper limb, they are adapted less for precision than for the strength needed to stand, maintain balance, walk, and run. Several of them cross and act upon two or more joints, such as the hip and knee. To avoid confusion in this discussion, remember that in the anatomical sense the word *leg* refers only to that part of the limb between the knee and ankle. The *foot* includes the tarsal region, metatarsal region, and toes. The next four tables group the muscles of the lower limb into those that act on the thigh and hip joint, those that act on the leg and knee joint, extrinsic (leg) muscles that act on the foot and ankle joint, and intrinsic (foot) muscles that act on the arches and toes.

10.5a Muscles Acting on the Hip and Thigh

The hip joint and thigh are acted on by muscles arising from both the pelvic girdle and the femur (table 10.13).

Anterior Muscles of the Hip

Most muscles that act on the femur originate on the hip bone. The two principal anterior muscles are the **iliacus**, which fills most of the broad iliac fossa of the pelvis, and the **psoas major**, a thick rounded muscle that arises mainly from the lumbar vertebrae

FIGURE 10.33 Muscles that Act on the Hip and Femur (Anterior View). **APR**

(fig. 10.33). Collectively, they are called the **iliopsoas** and share a common tendon to the femur.

Lateral and Posterior Muscles of the Hip

On the lateral and posterior sides of the hip are the **tensor fasciae latae** and three gluteal muscles. The **fascia lata** is a fibrous sheath that encircles the thigh like a subcutaneous stocking and tightly binds its muscles. On the lateral surface, it combines with the tendons of the gluteus maximus and tensor fasciae latae to form the **iliotibial tract**, which extends from the iliac crest to the lateral condyle of the tibia (see fig. 10.34; table 10.14). The tensor fasciae latae tautens the iliotibial tract and braces the knee, especially when the opposite foot is lifted.

FIGURE 10.34 Posterior Gluteal and Thigh Muscles. The left side shows the superficial muscles. On the right, the gluteus medius and maximus are removed to show the deeper gluteus minimus, lateral rotator group, and hamstring origins. The oblique white tendinous band across the semitendinosus is not always present. **APR**

? Describe two everyday movements of the body that employ the power of the gluteus maximus.

The gluteal muscles are the **gluteus maximus**, **gluteus medius**, and **gluteus minimus** (fig. 10.34). The gluteus maximus is the largest of these and forms most of the lean mass of the buttock. It is an extensor of the hip joint that produces the backswing of the leg in walking and provides most of the lift when you climb stairs. It generates its maximum force when the thigh is flexed at a 45° angle to the trunk. This is the advantage in starting a foot race from a crouched position. The gluteus medius is deep and lateral to the gluteus maximus. Its name refers to its size, not its position. The gluteus minimus is the smallest and deepest of the three.

Medial (Adductor) Compartment of the Thigh

Fasciae divide the thigh into three compartments: the anterior (extensor), posterior (flexor), and medial (adductor)

compartments (see fig. 10.41). Muscles of the anterior and posterior compartments function mainly as extensors and flexors of the knee, respectively, and are treated in table 10.14. The five muscles of the medial compartment act primarily as adductors of the thigh (see fig. 10.33), but some of them cross both the hip and knee joints and have additional actions as follows.

Lateral Rotators

Inferior to the gluteus minimus and deep to the other two gluteal muscles are six muscles called the **lateral rotators**, named for their action on the femur (fig. 10.34). Their action is most clearly visualized when you cross your legs to rest an ankle on

TABLE 10.13 Muscles Acting on the Hip and Thigh

Name	Action	Skeletal Attachments	Innervation
Anterior Muscles of the Hip			
Iliacus ⁷² (ih-LY-uh-cus)	Flexes thigh at hip when trunk is fixed; flexes trunk at hip when thigh is fixed, as in bending forward in a chair or sitting up in bed; balances trunk during sitting	- Iliac crest and fossa; superolateral region of sacrum; anterior sacroiliac and iliolumbar ligaments - Lesser trochanter and nearby shaft of femur	Femoral nerve
Psoas ⁷³ major (SO-ass)	Same as iliacus	- Bodies and intervertebral discs of vertebrae T12–L5; transverse processes of lumbar vertebrae - Lesser trochanter and nearby shaft of femur	Anterior rami of lumbar spinal nerves
Lateral and Posterior Muscles of the Hip			
Tensor fasciae latae ⁷⁴ (TEN-sur FASH-ee-ee LAY-tee)	Extends knee, laterally rotates tibia, aids in abduction and medial rotation of femur; during standing, steadies pelvis on femoral head and steadies femoral condyles on tibia	- Iliac crest; anterior superior spine; deep surface of fascia lata - Lateral condyle of tibia via iliotibial tract	Superior gluteal nerve
Gluteus maximus ⁷⁵	Extends thigh at hip as in stair climbing (rising to next step) or running and walking (backswing of limb); abducts thigh; elevates trunk after stooping; prevents trunk from pitching forward during walking and running; helps stabilize femur on tibia	- Posterior gluteal line of ilium, on posterior surface from iliac crest to posterior superior spine; coccyx; posterior surface of lower sacrum; aponeurosis of erector spinae - Gluteal tuberosity of femur; lateral condyle of tibia via iliotibial tract	Inferior gluteal nerve
Gluteus medius and gluteus minimus	Abduct and medially rotate thigh; during walking, shift weight of trunk toward limb with foot on the ground as other foot is lifted	- Most of lateral surface of ilium between crest and acetabulum - Greater trochanter of femur	Superior gluteal nerve
Medial (Adductor) Compartment of the Thigh			
Adductor brevis	Adducts thigh	- Body and inferior ramus of pubis - Linea aspera and spiral line of femur	Obturator nerve
Adductor longus	Adducts and medially rotates thigh; flexes thigh at hip	- Body and inferior ramus of pubis - Linea aspera of femur	Obturator nerve
Adductor magnus	Adducts and medially rotates thigh; extends thigh at hip	- Inferior ramus of pubis; ramus and tuberosity of ischium - Linea aspera, gluteal tuberosity, and medial supracondylar line of femur	Obturator nerve; tibial nerve
Gracilis ⁷⁶ (GRASS-ih-lis)	Flexes and medially rotates tibia at knee	- Body and inferior ramus of pubis; ramus of ischium - Medial surface of tibia just below condyle	Obturator nerve
Pectineus ⁷⁷ (pec-TIN-ee-us)	Flexes and adducts thigh	- Superior ramus of pubis - Spiral line of femur	Femoral nerve
Lateral Rotators			
Gemellus ⁷⁸ superior (jeh-MEL-us)	Laterally rotates extended thigh; abducts flexed thigh; sometimes absent	- Ischial spine - Greater trochanter of femur	Nerve to obturator internus
Gemellus inferior	Same actions as gemellus superior	- Ischial tuberosity - Greater trochanter of femur	Nerve to quadratus femoris
Obturator ⁷⁹ externus (OB-too-RAY-tur)	Not well understood; thought to laterally rotate thigh in climbing	- External surface of obturator membrane; rami of pubis and ischium - Femur between head and greater trochanter	Obturator nerve

⁷²*ili* = loin, flank⁷³*psoa* = loin⁷⁴*fasc* = band; *lat* = broad⁷⁵*glut* = buttock; *maxim* = largest⁷⁶*gracil* = slender⁷⁷*pectin* = comb⁷⁸*gemellus* = twin⁷⁹*obtur* = to close, stop up

TABLE 10.13 Muscles Acting on the Hip and Thigh (continued)

Name	Action	Skeletal Attachments	Innervation
Lateral Rotators (continued)			
Obturator internus	Not well understood; thought to laterally rotate extended thigh and abduct flexed thigh	• Ramus of ischium; inferior ramus of pubis; antero-medial surface of lesser pelvis • Greater trochanter of femur	Nerve to obturator internus
Piriformis ⁸⁰ (PIR-ih-FOR-mis)	Laterally rotates extended thigh; abducts flexed thigh	• Anterior surface of sacrum; gluteal surface of ilium; capsule of sacroiliac joint • Greater trochanter of femur	Spinal nerves L5–S2
Quadratus femoris ⁸¹ (quad-RAY-tus FEM-oh-ris)	Laterally rotates thigh	• Ischial tuberosity • Intertrochanteric crest of femur	Nerve to quadratus femoris

your knee, causing your femur to rotate and the knee to point laterally. Thus, they oppose medial rotation by the gluteus medius and minimus. Most of them also abduct or adduct the femur. The abductors are important in walking because when one lifts a foot from the ground, they shift the body weight to the other leg and prevent falling.

10.5b Muscles Acting on the Knee and Leg

The following muscles (table 10.14) form most of the mass of the thigh and produce their most obvious actions on the knee joint. Some of them, however, cross both the hip and knee joints and produce actions at both, moving the femur, tibia, and fibula.

Anterior (Extensor) Compartment of the Thigh

The anterior compartment of the thigh contains the large **quadriceps femoris**, the prime mover of knee extension and the most powerful muscle of the body (figs. 10.35, 10.36). As the name *quadriceps* implies, it has four heads: the **rectus femoris**, **vastus lateralis**, **vastus medialis**, and **vastus intermedius**. All four converge on a single **quadriceps (patellar) tendon**, which extends to the patella, then continues as the **patellar ligament** and inserts on the tibial tuberosity. (Remember that a tendon usually extends from muscle to bone, and a ligament from bone to bone.) The patellar ligament is struck with a rubber reflex hammer to test the knee-jerk reflex. The quadriceps extends the knee when you stand up, take a step, or kick a ball. One head, the rectus femoris, contributes to running by acting with the iliopsoas to flex the hip in each airborne phase of the leg's cycle of motion. The rectus femoris also flexes the hip in such actions as high kicks, stair climbing, or simply drawing the leg forward during a stride.

Crossing the quadriceps from the lateral side of the hip to the medial side of the knee is the narrow, straplike **sartorius**, the

**FIGURE 10.35** Superficial Muscles of the Right Thigh.

Anterior view.

Rebecca Gray/McGraw Hill

longest muscle of the body. It flexes the hip and knee joints and laterally rotates the thigh, as in crossing the legs. It is colloquially called the “tailor’s muscle” after the cross-legged posture of a tailor supporting his work on the raised knee.

⁸⁰*piri* = pear; *form* = shaped⁸¹*quadrat* = four-sided; *femoris* = of the thigh or femur

FIGURE 10.36 Anterior Muscles of the Right Thigh. (a) Superficial muscles. (b) Rectus femoris and other muscles removed to expose the other three heads of the quadriceps femoris. **APR**

Posterior (Flexor) Compartment of the Thigh

The posterior compartment contains three muscles colloquially known as the **hamstring muscles**; from lateral to medial, they are the **biceps femoris**, **semitendinosus**, and **semimembranosus** (see fig. 10.34). The pit at the back of the knee, known anatomically as the **popliteal fossa**, is colloquially called the *ham*. The tendons of these muscles can be felt as prominent cords on both sides of the fossa—the biceps tendon on the lateral side and the semimembranosus and semitendinosus tendons on the medial side. When wolves attack large prey, they instinctively attempt to sever the hamstring tendons, because this renders the prey helpless. The hamstrings flex the knee, and aided by the gluteus maximus, they extend the hip during walking and running. The semitendinosus is named for its unusually long tendon. This muscle also is usually bisected by a transverse or oblique tendinous band. The semimembranosus is named for the flat shape of its superior attachment.

Posterior Compartment of the Leg

Most muscles in the posterior compartment of the leg act on the ankle and foot and are reviewed in table 10.15, but the **popliteus** acts on the knee (see figs. 10.39, 10.40).

10.5c Muscles Acting on the Ankle and Foot

The fleshy mass of the leg is formed by a group of crural muscles (table 10.15), which act on the foot (fig. 10.37). These muscles are tightly bound by fasciae that compress them and aid in the return of blood from the legs. The fasciae separate the crural muscles into anterior, lateral, and posterior compartments (see fig. 10.41b).

Anterior (Extensor) Compartment of the Leg

Muscles of the anterior compartment dorsiflex the ankle and prevent the toes from scuffing the ground during walking. From lateral to medial, these muscles are the **fibularis tertius**, **extensor digitorum longus** (extensor of toes II–V), **extensor hallucis longus** (extensor of the great toe), and **tibialis anterior** (fig. 10.38). Their tendons are held tightly against the ankle and kept from bowing by two **extensor retinacula** similar to the one at the wrist. Inflammation of these tendons is one of the causes of *shinsplints* (see Deeper Insight 10.6).

TABLE 10.14 Muscles Acting on the Knee and Leg

Name	Action	Skeletal Attachments	Innervation
Anterior (Extensor) Compartment of the Thigh			
Quadriceps femoris (QUAD-rih-seps FEM-oh-ris)	Extends the knee, in addition to the actions of individual heads noted subsequently	- Varies; see individual heads - Patella; tibial tuberosity; lateral and medial condyles of tibia	Femoral nerve
Rectus femoris	Extends knee; flexes thigh at hip; flexes trunk on hip if thigh is fixed	- Ilium at anterior inferior spine and superior margin of acetabulum; capsule of hip joint - See quadriceps femoris	Femoral nerve
Vastus ⁸² lateralis	Extends knee; retains patella in groove on femur during knee movements	- Femur at greater trochanter and intertrochanteric line, gluteal tuberosity, and linea aspera - See quadriceps femoris	Femoral nerve
Vastus medialis	Same as vastus lateralis	- Femur at intertrochanteric line, spiral line, linea aspera, and medial supracondylar line - See quadriceps femoris	Femoral nerve
Vastus intermedius	Extends knee	- Anterior and lateral surfaces of femoral shaft - See quadriceps femoris	Femoral nerve
Sartorius ⁸³	Aids in knee and hip flexion, as in sitting or climbing; abducts and laterally rotates thigh	- On and near anterior superior spine of ilium - Medial surface of proximal end of tibia	Femoral nerve
Posterior (Flexor) Compartment of the Thigh			
Biceps femoris	Flexes knee; extends hip; elevates trunk from stooping posture; laterally rotates tibia on femur when knee is flexed; laterally rotates femur when hip is extended; counteracts forward bending at hips	- Long head: ischial tuberosity - Short head: linea aspera and lateral supracondylar line of femur - Head of fibula	Tibial nerve; common fibular nerve
Semitendinosus ⁸⁴ (SEM-ee-TEN-din-OH-sus)	Flexes knee; medially rotates tibia on femur when knee is flexed; medially rotates femur when hip is extended; counteracts forward bending at hips	- Ischial tuberosity - Medial surface of upper tibia	Tibial nerve
Semimembranosus ⁸⁵ (SEM-ee-MEM-bran-OH-sus)	Same as semitendinosus	- Ischial tuberosity - Medial condyle and nearby margin of tibia; intercondylar line and lateral condyle of femur; ligament of popliteal region	Tibial nerve
Posterior Compartment of the Leg			
Popliteus ⁸⁶ (pop-LIT-ee-us)	Rotates tibia medially on femur if femur is fixed (as in sitting down), or rotates femur laterally on tibia if tibia is fixed (as in standing up); unlocks knee to allow flexion; may prevent forward dislocation of femur during crouching	- Lateral condyle of femur; lateral meniscus and joint capsule - Posterior surface of upper tibia	Tibial nerve

⁸²vastus = large, extensive⁸³sartor = tailor⁸⁴semi = half; tendinosus = tendinous⁸⁵semi = half; membranosus = membranous⁸⁶poplit = ham (pit) of the knee

DEEPER INSIGHT 10.6

CLINICAL APPLICATION

Shinsplints

Shinsplints is a general term embracing several kinds of injury with pain in the crural region: tendinitis of the tibialis posterior muscle, inflammation of the tibial periosteum, and anterior compartment syndrome. Shinsplints can result from unaccustomed jogging, walking on snowshoes, or any vigorous activity of the legs after a period of relative inactivity.

Posterior (Flexor) Compartment of the Leg, Superficial Group

The posterior compartment has superficial and deep muscle groups (**fig. 10.39**). The three muscles of the superficial group are plantar flexors: the **gastrocnemius**, **soleus**, and **plantaris**. The first two of these, collectively known as the **triceps surae**,⁸⁷ insert on the calcaneus by way of the **calcaneal (Achilles) tendon**. This is the

strongest tendon of the body but is nevertheless a common site of sports injuries resulting from sudden stress (see Deeper Insight 10.7). The *plantaris*, a weak synergist of the triceps surae, is a relatively unimportant muscle and is absent from many people; it is not tabulated here. Surgeons often use the plantaris tendon for tendon grafts needed in other parts of the body.

Posterior (Flexor) Compartment of the Leg, Deep Group

There are four muscles in the deep group (**fig. 10.40**). The **flexor digitorum longus**, **flexor hallucis longus**, and **tibialis posterior** are plantar flexors. The fourth muscle, the *popliteus*, is described in table 10.14 because it acts on the knee rather than on the foot.

Lateral (Fibular) Compartment of the Leg

The lateral compartment includes the **fibularis brevis** and **fibularis longus** (see **figs. 10.37a, 10.38a; fig. 10.41**). They plantar flex and evert the foot. Plantar flexion is important not only in standing on tiptoes but in providing lift and forward thrust each time you take a step.

⁸⁷*tri* = three; *ceps* = heads; *surae* = of the calf

FIGURE 10.38 Muscles of the Right Leg, Anterior Compartment. Boldface labels indicate muscles belonging to the anterior compartment. (a) Superficial anterior view of the leg. Some muscles of the posterior and lateral compartments are also partially visible. (b)–(d) Individual muscles of the anterior compartment of the leg and dorsal aspect of the foot. **APR**

CLINICAL APPLICATION

Calcaneal Tendon Rupture

Calcaneal tendon rupture is a common injury experienced in amateur, strenuous sports such as basketball and tennis. When pushing off strongly from the ground as in a basketball jump shot, the tendon may rupture with a loud pop, described by some as sounding like a gunshot. The rupture causes pain just above the heel and inability to stand or walk on the affected leg. Two visible signs of a ruptured tendon are a large knot, the contracted triceps surae, in the upper calf; and abnormal dorsiflexion of the foot, caused by the action of the tibialis anterior

suddenly unfettered by the opposing action of the triceps. Calcaneal tendon rupture is most common in overweight men, 30 to 40 years old, who are not in great physical condition but partake in an unaccustomed game such as pickup basketball or backyard football. A ruptured tendon can often heal on its own with rest and proper care, but may require surgical repair, especially in young physically active people not inclined to rest it for months.

TABLE 10.15 Muscles Acting on the Ankle and Foot

Name	Action	Skeletal Attachments	Innervation
Anterior (Extensor) Compartment of the Leg			
Fibularis (peroneus ⁸⁸) tertius ⁸⁹ (FIB-you-LERR-iss TUR-she-us)	Dorsiflexes and everts foot during walking; helps toes clear the ground during forward swing of leg	• Medial surface of lower one-third of fibula; interosseous membrane • Metatarsal V	Deep fibular (peroneal) nerve
Extensor digitorum longus (DIDJ-ih-TOE-rum)	Extends toes; dorsiflexes foot; tautens plantar aponeurosis	• Lateral condyle of tibia; shaft of fibula; interosseous membrane • Middle and distal phalanges II–V	Deep fibular (peroneal) nerve
Extensor hallucis longus (ha-LOO-sis)	Extends great toe; dorsiflexes foot	• Anterior surface of middle of fibula, interosseous membrane • Distal phalanx I	Deep fibular (peroneal) nerve
Tibialis ⁹⁰ anterior (TIB-ee-AY-lis)	Dorsiflexes and inverts foot; resists backward tipping of body (as when standing on a moving boat deck); helps support medial longitudinal arch of foot	• Lateral condyle and lateral margin of proximal half of tibia; interosseous membrane • Medial cuneiform, metatarsal I	Deep fibular (peroneal) nerve
Posterior (Flexor) Compartment of the Leg, Superficial Group			
Gastrocnemius ⁹¹ (GAS-trock-NEE-me-us)	Plantar flexes foot, flexes knee; active in walking, running, and jumping	• Condyles, popliteal surface, and lateral supracondylar line of femur; capsule of knee joint • Calcaneus	Tibial nerve
Soleus ⁹² (SO-lee-us)	Plantar flexes foot; steadies leg on ankle during standing	• Posterior surface of head and proximal one-fourth of fibula; middle one-third of tibia; interosseous membrane • Calcaneus	Tibial nerve
Posterior (Flexor) Compartment of the Leg, Deep Group			
Flexor digitorum longus	Flexes phalanges of digits II–V as foot is raised from ground; stabilizes metatarsal heads and keeps distal pads of toes in contact with ground in toe-off and tiptoe movements	• Posterior surface of tibial shaft • Distal phalanges II–V	Tibial nerve
Flexor hallucis longus	Same actions as flexor digitorum longus, but for great toe (digit I)	• Distal two-thirds of fibula and interosseous membrane • Distal phalanx I	Tibial nerve
Tibialis posterior	Inverts foot; may assist in strong plantar flexion or control pronation of foot during walking	• Posterior surface of proximal half of tibia, fibula, and interosseous membrane • Navicular, medial cuneiform, metatarsals II–IV	Tibial nerve
Lateral (Fibular) Compartment of the Leg			
Fibularis (peroneus) brevis	Maintains concavity of sole during toe-off and tiptoeing; may evert foot and limit inversion and help steady leg on foot	• Lateral surface of distal two-thirds of fibula • Base of metatarsal V	Superficial fibular (peroneal) nerve
Fibularis (peroneus) longus	Maintains concavity of sole during toe-off and tiptoeing; everts and plantar flexes foot	• Head and lateral surface of proximal two-thirds of fibula • Medial cuneiform, metatarsal I	Superficial fibular (peroneal) nerve

⁸⁸*perone* = pinlike (fibula)⁸⁹*fibularis* = of the fibula; *tert* = third⁹⁰*tibialis* = of the tibia⁹¹*gastro* = belly; *cnem* = leg⁹²Named for its resemblance to a flatfish (sole)

FIGURE 10.41 Serial Cross Sections Through the Right Lower Limb. Cross sections of the femur (a) and leg (b) are taken at the correspondingly lettered levels in the figure at the left.

▶▶▶ APPLY WHAT YOU KNOW

Suppose you tilt your foot upward to trim or paint your toenails. Identify as many muscles as you know that can contribute to this action.

▶▶▶ APPLY WHAT YOU KNOW

Suppose you are playing Frisbee and your Frisbee lands on the roof of your house. You have to climb a ladder to get it. Identify as many muscles as you can that would aid you in ascending from one rung of the ladder to the next.

10.5d Intrinsic Muscles of the Foot

The intrinsic muscles of the foot (**table 10.16**) help to support the arches and act on the toes in ways that aid locomotion. Several of them are similar in name and location to the intrinsic muscles of the hand.

Dorsal (Superior) Aspect of the Foot

Only one of the intrinsic muscles, the **extensor digitorum brevis**, is on the dorsal (superior) side of the foot. The medial slip of this

muscle, serving the great toe, is sometimes called the *extensor hallucis brevis*.

Ventral Layer 1 (Most Superficial)

All remaining intrinsic muscles are on the ventral (inferior) aspect of the foot or between the metatarsal bones. They are grouped in four layers (**fig. 10.42**). Dissecting into the foot from the plantar surface, one first encounters a tough fibrous sheet, the **plantar aponeurosis**, between the skin and muscles. It diverges like a fan from the calcaneus to the bases of all the toes, and is a common site of painful inflammation (see Deeper Insight 10.8). Several ventral muscles arise from this aponeurosis. The ventral muscles include the stout **flexor digitorum brevis** on the midline of the foot, with four tendons that supply all digits except the great toe. It is flanked by the **abductor digiti minimi** laterally and the **abductor hallucis** medially.

Ventral Layer 2

The next deeper layer consists of the thick **quadratus plantae (flexor accessorius)** in the middle of the foot and the four **lumbrical muscles** located between the metatarsals.

FIGURE 10.42 Intrinsic Muscles of the Right Foot. (a)–(d) First through fourth layers, respectively, in ventral (plantar) views. (e) Fourth layer, dorsal view. The muscles belonging to each layer are shown in color and with boldface labels. **APR**

DEEPER INSIGHT 10.8

CLINICAL APPLICATION

Plantar Fasciitis

Plantar fasciitis (FASH-ee-EYE-tis) is inflammation of the plantar aponeurosis, typically felt as a recurring pain in the heel and medial aspect of the foot. The pain is often most severe when one begins to walk after prolonged sitting or when rising from bed. It usually subsides in 5 to

10 minutes, but occurs again after the next period of rest. Dorsiflexion of the foot often intensifies the pain. Plantar fasciitis typically results from excessive or unaccustomed running and high-impact aerobics, especially in persons who don't wear properly supportive athletic footwear.

TABLE 10.16 Intrinsic Muscles of the Foot

Name	Action	Skeletal Attachments	Innervation
Dorsal (Superior) Aspect of Foot			
Extensor digitorum brevis	Extends proximal phalanx I and all phalanges of digits II–IV	• Calcaneus; inferior extensor retinaculum of ankle • Proximal phalanx I, tendons of extensor digitorum longus to middle and distal phalanges II–IV	Deep fibular (peroneal) nerve
Ventral Layer 1 (Most Superficial)			
Flexor digitorum brevis	Flexes digits II–IV; supports arches of foot	• Calcaneus; plantar aponeurosis • Middle phalanges II–V	Medial plantar nerve
Abductor digiti minimi ⁹³	Abducts and flexes little toe; supports arches of foot	• Calcaneus; plantar aponeurosis • Proximal phalanx V	Lateral plantar nerve
Abductor hallucis	Abducts great toe; supports arches of foot	• Calcaneus; plantar aponeurosis; flexor retinaculum • Proximal phalanx I	Medial plantar nerve
Ventral Layer 2			
Quadratus plantae ⁹⁴ (quad-RAY-tus PLAN-tee)	Same as flexor digitorum longus (table 10.15); flexion of digits II–V and associated locomotor functions	• Two heads on the medial and lateral sides of calcaneus • Distal phalanges II–V via flexor digitorum longus tendons	Lateral plantar nerve
Four lumbrical muscles (LUM-brih-cul)	Flex toes II–V	• Tendon of flexor digitorum longus • Proximal phalanges II–V	Lateral and medial plantar nerves
Ventral Layer 3			
Flexor digiti minimi brevis	Flexes little toe	• Metatarsal V, sheath of fibularis longus • Proximal phalanx V	Lateral plantar nerve
Flexor hallucis brevis	Flexes great toe	• Cuboid; lateral cuneiform; tibialis posterior tendon • Proximal phalanx I	Medial plantar nerve
Adductor hallucis	Adducts great toe	• Metatarsals II–IV; fibularis longus tendon; ligaments at bases of digits III–V • Proximal phalanx I	Lateral plantar nerve
Ventral Layer 4 (Deepest)			
Four dorsal interosseous muscles	Abduct toes II–IV	• Each with two heads arising from facing surfaces of two adjacent metatarsals • Proximal phalanges II–IV	Lateral plantar nerve
Three plantar interosseous muscles	Adduct toes III–V	• Medial aspect of metatarsals III–V • Proximal phalanges III–V	Lateral plantar nerve

⁹³digit = toe; minim = smallest

⁹⁴quadrat = four-sided; plantae = of the plantar region

Ventral Layer 3

The muscles of this layer serve only the great and little toes. They are the **flexor digiti minimi brevis**, **flexor hallucis brevis**, and **adductor hallucis**. The adductor hallucis has an oblique head that extends diagonally from the midplantar region to the base of the great toe, and a transverse head that passes across the bases of digits II–IV and meets the long head at the base of the great toe.

Ventral Layer 4 (Deepest)

This layer consists only of the small interosseous muscles located between the metatarsal bones—four dorsal and three plantar. Each **dorsal interosseous muscle** is bipennate and originates on two adjacent metatarsals. The **plantar interosseous muscles** are unipennate and originate on only one metatarsal each.

▶▶▶ APPLY WHAT YOU KNOW

Not everyone has the same muscles. From the information provided in this chapter, identify at least three muscles that are lacking in some people.

DEEPER INSIGHT 10.9

CLINICAL APPLICATION

Common Athletic Injuries

Although the muscular system is subject to fewer diseases than most organ systems, it is particularly vulnerable to injuries resulting from sudden and intense stress placed on muscles and tendons. Each year, thousands of athletes from the high-school to professional level sustain some type of injury to their muscles, as do the increasing numbers of people who have taken up running and other forms of physical conditioning. Overzealous exertion without proper conditioning and warm-up is frequently the cause. This chapter has already described several examples: compartment syndrome, rotator cuff injury, shin-splints, calcaneal tendon rupture, and plantar fasciitis. A few more are described here.

Baseball finger—tears in the extensor tendons of the fingers resulting from the impact of a baseball with the extended fingertip.

Blocker's arm—abnormal calcification in the lateral margin of the forearm as a result of repeated impact with opposing players.

Charley horse—any painful tear, stiffness, and blood clotting in a muscle. A charley horse of the quadriceps femoris is often caused by football tackles.

Pitcher's arm—inflammation at the proximal attachment of the flexor carpi muscles resulting from hard wrist flexion in releasing a baseball.

Pulled groin—strain in the adductor muscles of the thigh; common in gymnasts and dancers who perform splits and high kicks.

Pulled hamstrings—strained hamstring muscles or a partial tear in their tendons, often with a hematoma (blood clot) in the fascia lata. This condition is frequently caused by repetitive kicking (as in football and soccer) or long, hard running.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

22. In the middle of a stride, you have one foot on the ground and you are about to swing the other leg forward. What muscles produce the movements of that leg?
23. Name the muscles that cross both the hip and knee joints and produce actions at both.
24. List the major actions of the muscles of the anterior, medial, and posterior compartments of the thigh.
25. Describe the roles of plantar flexion and dorsiflexion in walking. What muscles produce these actions?

Tennis elbow—inflammation at the proximal attachment of the extensor carpi muscles on the lateral epicondyle of the humerus. It occurs when these muscles are repeatedly tensed during backhand strokes and then strained by sudden impact with the tennis ball. Any activity that requires rotary movements of the forearm and a firm grip of the hand (for example, using a screwdriver) can cause the symptoms of tennis elbow.

Most athletic injuries can be prevented by proper conditioning. A person who suddenly takes up vigorous exercise may not have sufficient muscle and bone mass to withstand the stresses such exercise entails. These must be developed gradually. Stretching exercises keep ligaments and joint capsules supple and therefore reduce injuries. Warm-up exercises promote more efficient and less injurious musculoskeletal function in several ways. Most of all, moderation is important, as most injuries simply result from overuse of the muscles. “No pain, no gain” is a risky misconception.

Muscular injuries can be treated initially with “RICE”: rest, ice, compression, and elevation. Rest prevents further injury and allows repair processes to occur; ice reduces swelling; compression with an elastic bandage helps to prevent fluid accumulation and swelling; and elevation of an injured limb promotes drainage of blood from the affected area and limits further swelling. If these measures are not enough, anti-inflammatory drugs may be employed, including corticosteroids as well as aspirin and other nonsteroidal agents. Serious injuries, such as compartment syndrome, require emergency attention by a physician.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

10.1 Structural and Functional Organization of Muscles

1. Which muscles are included in the muscular system and which ones are not; the name of the science that specializes in the muscular system
2. Functions of the muscular system
3. The relationship of muscle structure to the endomysium, perimysium, and epimysium; what constitutes a fascicle of skeletal muscle and how it relates to these connective tissues; and the relationship of a fascia to a muscle
4. Classification of muscles according to the orientation of their fascicles
5. Muscle compartments, interosseous membranes, and intermuscular septa
6. Direct, indirect, moving, and stationary muscle attachments
7. The flaw in *origin–insertion* terminology of muscle attachments
8. The action of a muscle; how it relates to the classification of muscles as *prime movers*, *synergists*, *antagonists*, or *fixators*; why these terms are not fixed for a given muscle but differ from one joint movement to another, and examples to illustrate this point
9. Intrinsic versus extrinsic muscles, with examples
10. The nerve and blood supplies to muscles
11. Features to which the Latin names of muscles commonly refer, with examples

10.2 Muscles of the Head and Neck

Know the locations, actions, skeletal attachments, and innervations of the named muscles in each of the following groups, and be able to recognize them on laboratory specimens or models to the extent required in your course.

1. The occipitofrontalis muscle of the scalp, eyebrows, and forehead (table 10.1)
2. The orbicularis oculi, levator palpebrae superioris, and corrugator supercilii muscles, which move the eyelid and other tissues around the eye (table 10.1)
3. The nasalis muscle, which flares and compresses the nostrils (table 10.1)
4. The orbicularis oris, levator labii superioris, levator anguli oris, zygomaticus major and minor, risorius, depressor

anguli oris, depressor labii inferioris, and mentalis muscles, which act on the lips (table 10.1)

5. The buccinator muscles of the cheeks (table 10.1)
6. The platysma, which acts upon the mandible and the skin of the neck (table 10.1)
7. The intrinsic muscles of the tongue in general, and specific extrinsic muscles: the genioglossus, hyoglossus, styloglossus, and palatoglossus muscles (table 10.2)
8. The temporalis, masseter, medial pterygoid, and lateral pterygoid muscles of biting and chewing (table 10.2)
9. The suprahyoid group: the digastric, geniohyoid, mylohyoid, and stylohyoid muscles (table 10.2)
10. The infrahyoid group: the omohyoid, sternohyoid, thyrohyoid, and sternothyroid muscles (table 10.2)
11. The superior, middle, and inferior pharyngeal constrictor muscles of the throat (table 10.2)
12. The sternocleidomastoid and three scalene muscles, which flex the neck, and the trapezius, splenius capitis, and semispinalis capitis muscles, which extend it (table 10.3)

10.3 Muscles of the Trunk

For the following muscles, know the same information as for section 10.2.

1. The diaphragm and the external intercostal, internal intercostal, and innermost intercostal muscles of respiration (table 10.4)
2. The external oblique, internal oblique, transverse abdominal, and rectus abdominis muscles of the anterior and lateral abdominal wall (table 10.5)
3. The superficial erector spinae muscle (and its subdivisions) and the deep semispinalis thoracis, quadratus lumborum, and multifidus muscles of the back (table 10.6)
4. The perineum, its two triangles, and their skeletal landmarks (table 10.7)
5. The ischiocavernosus and bulbospongiosus muscles of the superficial perineal space of the pelvic floor (table 10.7)
6. The deep transverse perineal muscle, and in females, the compressor urethrae of the deep perineal space of the pelvic floor, and the external anal sphincter of the anal triangle (table 10.7)

7. The levator ani muscle of the pelvic diaphragm, the deepest compartment of the pelvic floor (table 10.7)

10.4 Muscles Acting on the Shoulder and Upper Limb

For the following muscles, know the same information as for section 10.2.

1. The pectoralis minor, serratus anterior, trapezius, levator scapulae, rhomboid major, and rhomboid minor muscles of scapular movement (table 10.8)
2. Muscles that act on the humerus, including the pectoralis major, latissimus dorsi, deltoid, teres major, coracobrachialis, and four rotator cuff (SITS) muscles—the supraspinatus, infraspinatus, teres minor, and subscapularis (table 10.9)
3. The brachialis, biceps brachii, triceps brachii, brachioradialis, anconeus, pronator quadratus, pronator teres, and supinator muscles of forearm movement (table 10.10)
4. The relationship of the flexor retinaculum, extensor retinaculum, and carpal tunnel to the tendons of the forearm muscles
5. The palmaris longus, flexor carpi radialis, flexor carpi ulnaris, and flexor digitorum superficialis muscles of the superficial anterior compartment of the forearm, and the flexor digitorum profundus and flexor pollicis longus muscles of the deep anterior compartment (table 10.11)
6. The extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum, extensor digiti minimi, and extensor carpi ulnaris muscles of the superficial posterior compartment (table 10.11)
7. The abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, and extensor indicis muscles of the deep posterior compartment (table 10.11)
8. The thenar group of intrinsic hand muscles: adductor pollicis, abductor pollicis brevis, flexor pollicis brevis, and opponens pollicis (table 10.12)
9. The hypothenar group of intrinsic hand muscles: abductor digiti minimi, flexor digiti minimi brevis, and opponens digiti minimi (table 10.12)
10. The midpalmar group of intrinsic hand muscles: four dorsal interosseous muscles, three palmar interosseous muscles, and four lumbrical muscles (table 10.12)

STUDY GUIDE

10.5 Muscles Acting on the Hip and Lower Limb

For the following muscles, know the same information as for section 10.2.

1. The iliopsoas muscle of the hip, and its two subdivisions, the iliacus and psoas major (table 10.13)
2. The tensor fasciae latae, gluteus maximus, gluteus medius, and gluteus minimus muscles of the hip and buttock, and the relationship of the first two to the fascia lata and iliotibial tract (table 10.13)
3. The lateral rotators: gemellus superior, gemellus inferior, obturator externus, obturator internus, piriformis, and quadratus femoris muscles (table 10.13)
4. The compartments of the thigh muscles: anterior (extensor), medial (adductor), and posterior (flexor) compartments
5. Muscles of the medial compartment of the thigh: adductor brevis, adductor longus, adductor magnus, gracilis, and pectineus (table 10.13)
6. Muscles of the anterior compartment of the thigh: sartorius and quadriceps femoris, and the four heads of the quadriceps (table 10.14)
7. The hamstring muscles of the posterior compartment of the thigh: biceps femoris, semitendinosus, and semimembranosus (table 10.14)
8. The compartments of the leg muscles: anterior, posterior, and lateral (table 10.15)
9. Muscles of the anterior compartment of the leg: fibularis tertius, extensor digitorum longus, extensor hallucis longus, and tibialis anterior muscles of the anterior compartment (table 10.15)
10. Muscles of the superficial posterior compartment of the leg: popliteus and triceps surae (gastrocnemius and soleus), and the relationship of the triceps surae to the calcaneal tendon and calcaneus (table 10.15)
11. Muscles of the deep posterior compartment of the leg: flexor digitorum longus, flexor hallucis longus, and tibialis posterior muscles of the deep posterior compartment
12. Muscles of the lateral compartment of the leg: fibularis brevis and fibularis longus (table 10.15)
13. The extensor digitorum brevis of the dorsal aspect of the foot (table 10.16)
14. The four muscle compartments (layers) of the ventral aspect of the foot, and the muscles in each: the flexor digitorum brevis, abductor digiti minimi, and abductor hallucis (layer 1); the quadratus plantae and four lumbrical muscles (layer 2); the flexor digiti minimi brevis, flexor hallucis brevis, and adductor hallucis (layer 3); and the four dorsal interosseous muscles and three plantar interosseous muscles (layer 4) (table 10.16)

▶ Testing Your Recall

Answers in Appendix A

1. Which of the following muscles does *not* contribute to the rotator cuff?
 - a. teres minor
 - b. teres major
 - c. subscapularis
 - d. infraspinatus
 - e. supraspinatus
2. Make a fist, then straighten your fingers. The muscles that performed the latter action have tendons that pass through
 - a. the flexor retinaculum.
 - b. the extensor retinaculum.
 - c. the carpal tunnel.
 - d. the rotator cuff.
 - e. the plantar region of the wrist.
3. Which of these is *not* a suprahyoid muscle?
 - a. genioglossus
 - b. geniohyoid
 - c. stylohyoid
 - d. mylohyoid
 - e. digastric
4. Which of these muscles is an extensor of the neck?
 - a. external oblique
 - b. sternocleidomastoid
 - c. splenius capitis
 - d. iliocostalis
 - e. latissimus dorsi
5. Which of these muscles of the pelvic floor is the deepest?
 - a. superficial transverse perineal
 - b. bulbospongiosus
 - c. ischiocavernosus
 - d. deep transverse perineal
 - e. levator ani
6. Which of these actions is *not* performed by the trapezius?
 - a. extension of the neck
 - b. depression of the scapula
 - c. elevation of the scapula
 - d. rotation of the scapula
 - e. adduction of the humerus
7. Both the hands and feet are acted upon by a muscle or muscles called
 - a. the extensor digitorum.
 - b. the abductor digiti minimi.
 - c. the flexor digitorum profundus.
 - d. the abductor hallucis.
 - e. the flexor digitorum longus.
8. Which of the following muscles does *not* extend the hip joint?
 - a. quadriceps femoris
 - b. gluteus maximus
 - c. biceps femoris
 - d. semitendinosus
 - e. semimembranosus
9. Both the gastrocnemius and _____ muscles insert on the heel by way of the calcaneal tendon.
 - a. semimembranosus
 - b. tibialis posterior
 - c. tibialis anterior
 - d. soleus
 - e. plantaris
10. Which of the following muscles raises the upper lip?
 - a. levator palpebrae superioris
 - b. orbicularis oris
 - c. zygomaticus minor
 - d. masseter
 - e. mentalis
11. What muscle is the prime mover in sucking through a soda straw or spitting out a mouthful of liquid?
12. A bundle of muscle fibers surrounded by perimysium is called a/an _____.
13. The _____ is the muscle that generates the most force in a given joint movement.
14. The three large muscles on the posterior side of the thigh are commonly known as the _____ muscles.

STUDY GUIDE

15. Connective tissue bands called _____ prevent flexor tendons of the forearm and leg from rising like bowstrings.
16. The anterior half of the perineum is a region called the _____.
17. The abdominal aponeuroses converge on a median fibrous band on the abdomen called the _____.
18. A muscle that works with another to produce the same or similar movement is called a/an _____.
19. A muscle somewhat like a feather, with fibers obliquely approaching its tendon from both sides, is called a/an _____ muscle.
20. A circular muscle that closes a body opening is called a/an _____.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|------------|-----------|-----------|
| 1. capito- | 3. fasc- | 7. mys- |
| 2. ergo- | 4. labio- | 8. omo- |
| | 5. lumbo- | 9. penn- |
| | 6. mus- | 10. tert- |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|---|---|--|
| 1. Each skeletal muscle fiber is enclosed in a perimysium that separates it from adjacent fibers. | 4. A synergist is a muscle whose action is opposite that of an agonist. | 8. Severing the large trigeminal nerve would paralyze more facial muscles than severing the facial nerve. |
| 2. The orbicularis oris is a sphincter. | 5. Each skeletal muscle is innervated by at least one spinal nerve. | 9. The following intrinsic hand muscles are listed in order from strongest to weakest: abductor digiti minimi, adductor pollicis, dorsal interosseous. |
| 3. The biceps brachii is a bipennate muscle. | 6. One must contract the internal intercostal muscles in order to exhale. | 10. The tibialis anterior and tibialis posterior are synergists. |
| | 7. In climbing stairs, the hamstrings provide much of the thrust that lifts the body to each higher step. | |

► Testing Your Comprehension

- | | | |
|--|---|--|
| 1. Radical mastectomy, once a common treatment for breast cancer, involved removal of the pectoralis major along with the breast. What functional impairments would result from this? What synergists could a physical therapist train a patient to use to recover some lost function? | 3. Nerve damage often results in loss of muscle functions. State which nerve you think may be damaged if each of the following conditions was observed in a patient: (a) inability to open one eye; (b) paralysis of the diaphragm; (c) inability of a male to sustain an erection or clear the urethra of urine; (d) difficulty flexing or extending the elbow; and (e) inability to stand on tiptoes. | drome" when they go barefoot or wear flat shoes. What muscle(s) and tendon(s) are involved? Explain. |
| 2. Removal of cancerous lymph nodes from the neck sometimes requires removal of the sternocleidomastoid on that side. How would this affect a patient's range of head movement? | 4. People who wear high heels most of the time may suffer painful "high heel syn- | 5. A student moving out of a dormitory crouches, in correct fashion, to lift a heavy box of books. What prime movers are involved in straightening the legs to lift the box? |

REGIONAL AND SURFACE ANATOMY

How many muscles can you identify from their surface appearance?

Y Photo Studio/Shutterstock

ATLAS OUTLINE

B.1 Regional Anatomy

B.2 The Importance of Surface Anatomy

B.3 Learning Strategy

Figures B.1–B.2 The Head and Neck

Figures B.3–B.15 The Trunk

Figures B.16–B.19 The Upper Limb

Figures B.20–B.24 The Lower Limb

Figure B.25 Test of Muscle Recognition

B.1 Regional Anatomy

On the whole, this book takes a systems approach to anatomy, examining the structure and function of each organ system, one at a time, regardless of which body regions it may traverse. Physicians and surgeons, however, think and act in terms of regional anatomy. If a patient presents with pain in the lower right quadrant (see atlas A, fig. A.4a), the source may be the appendix, an ovary, or an inguinal muscle, among other possibilities. The question is to think not of an entire organ system (the esophagus is probably irrelevant to that quadrant), but of what organs are present in that region and what possibilities must be considered as the cause of the pain. This atlas presents several views of the body region by region so you can see some of the spatial relationships that exist among the organ systems considered in their separate chapters.

B.2 The Importance of Surface Anatomy

In the study of human anatomy, it is easy to become so preoccupied with internal structure that we forget the importance of what we can see and feel externally. Yet external anatomy and appearance are major concerns in giving a physical examination and in many aspects of patient care. A knowledge of the body's surface landmarks is essential to one's competence in physical therapy, cardiopulmonary resuscitation, surgery, making X-rays and electrocardiograms, giving injections, drawing blood, listening to heart and respiratory sounds, measuring the pulse and blood pressure, and finding pressure points to stop arterial bleeding, among other procedures. A misguided attempt to perform some of these procedures while disregarding or misunderstanding external anatomy can be very harmful and even fatal to a patient.

Having just studied skeletal and muscular anatomy in the preceding chapters, this is an opportune time for you to study the body surface. Much of what we see there reflects the underlying structure of the superficial bones and muscles. A broad photographic overview of surface anatomy is given in atlas A (see fig. A.3), where it is necessary for providing a vocabulary for reference in subsequent chapters. This atlas shows this surface anatomy in closer detail so you can relate it to the musculoskeletal anatomy of the three preceding chapters.

B.3 Learning Strategy

To make the most profitable use of this atlas, refer back to earlier chapters as you study these illustrations. Relate drawings of the clavicle in figure 8.32 to the photograph in figure B.1, for example. Study the shape of the scapula in figure 8.33 and see how much of it you can trace on the photographs in figure B.9. See if you can relate the tendons visible on the hand (see fig. B.19) to the muscles of the forearm illustrated in figures 10.29 and 10.30, and the external markings of the pelvic girdle (see fig. B.15) to bone structure in section 8.5a.

For learning surface anatomy, there is a resource available to you that is far more valuable than any laboratory model or textbook illustration—your own body. For the best understanding of human structure, compare the art and photographs in this book with your body or with structures visible on a study partner. In addition to bones and muscles, you can palpate a number of superficial arteries, veins, tendons, ligaments, and cartilages, among other structures. By palpating regions such as the shoulder, elbow, or ankle, you can develop a mental image of the subsurface structures better than the image you can obtain by looking at two-dimensional textbook images. And the more you can study with other people, the more you will appreciate the variations in human structure and be able to apply your knowledge to your future patients or clients, who will not look quite like any textbook diagram or photograph you have ever seen. Through comparisons of art, photography, and the living body, you will get a much deeper understanding of the body than if you were to study this atlas in isolation from the earlier chapters.

At the end of this atlas, you can test your knowledge of externally visible muscle anatomy. The two photographs in figure B.25 have 30 numbered muscles and a list of 26 names, some of which are shown more than once in the photographs and some of which are not shown at all. Identify the muscles to your best ability without looking back at the previous illustrations, and then check your answers in appendix A.

Module 6: Muscular System

BRUSHING UP

- You should be familiar with the organization of a typical skeletal muscle and its associated connective tissues (see section 10.1 b).
- You should know the basic neuron structure introduced in table 5.10 to understand the nerve–muscle relationship in this chapter.
- The stimulation of a muscle fiber by a neuron is based on principles of plasma membrane proteins as receptors and as ligand- and voltage-gated ion channels (see “Membrane Proteins” in section 3.2a).
- Section 1.6e, “Gradients and Flow,” provides a core concept (especially electrochemical gradients) for understanding muscle excitation and the activation of contraction.
- The differences between aerobic respiration and anaerobic fermentation (see fig. 2.31) are central to understanding exercise physiology and the energy metabolism of muscle.
- Familiarity with desmosomes and gap junctions (see section 5.5a) will enhance your appreciation of the fundamental properties of cardiac and smooth muscle.

Movement is a fundamental characteristic of all living organisms, from bacteria to humans. Even plants and other seemingly immobile organisms move cellular components from place to place. Across the entire spectrum of life, the molecular mechanisms of movement are very similar, involving motor proteins such as myosin and dynein. But in animals, movement has developed to the highest degree, with the evolution of muscle cells specialized for this function. A muscle cell is essentially a device for converting the chemical energy of ATP into the mechanical energy of movement.

The three types of muscular tissue—skeletal, cardiac, and smooth—are described and compared in table 5.11. Cardiac and smooth muscle are further described in this chapter, and cardiac muscle is discussed most extensively in chapter 19. Most of the present chapter, however, concerns skeletal muscle, the type that holds the body erect against the pull of gravity and produces its outwardly visible movements.

This chapter treats the structure, contraction, and metabolism of skeletal muscle at the molecular, cellular, and tissue levels of organization. Understanding muscle at these levels provides an indispensable basis for understanding such aspects of motor performance as quickness, strength, endurance, and fatigue. Such factors have obvious relevance to athletic performance, and they become very important when a lack of physical conditioning, old age, or injury interferes with a person's ability to carry out everyday tasks or meet the extra demands for speed or strength that we all occasionally encounter.

11.1 Types and Characteristics of Muscular Tissue

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the physiological properties that all muscle types have in common;
- list the defining characteristics of skeletal muscle; and
- discuss the elastic functions of the connective tissue components of a muscle.

11.1a Universal Characteristics of Muscle

The functions of the muscular system were detailed in the preceding chapter: movement, stability, communication, control of body openings and passages, heat production, and glycemic control. To carry out those functions, all muscle cells have the following characteristics.

- **Excitability (responsiveness).** Excitability is a property of all living cells, but muscle and nerve cells have developed this property to the highest degree. When stimulated by chemical signals, stretch, and other stimuli, muscle cells respond with electrical changes across the plasma membrane.
- **Conductivity.** Stimulation of a muscle cell produces more than a local effect. Local electrical excitation sets off a wave of excitation that travels rapidly along the cell and initiates processes leading to contraction.
- **Contractility.** Muscle cells are unique in their ability to shorten substantially when stimulated. This enables them to pull on bones and other organs to create movement.
- **Extensibility.** In order to contract, a muscle cell must also be extensible—able to stretch again between contractions. Most cells rupture if they are stretched even a little, but skeletal muscle cells can stretch to as much as three times their contracted length.
- **Elasticity.** When a muscle cell is stretched and then released, it recoils to a shorter length. If it were not for this elastic recoil, resting muscles would be too slack or flabby. Owing to a *length–tension relationship* to be described in this chapter, they wouldn't contract very strongly when stimulated.

11.1b Skeletal Muscle

Skeletal muscle is voluntary striated muscle that is usually attached to one or more bones. A skeletal muscle cell exhibits alternating light and dark transverse bands, or **striations** (fig. 11.1), that reflect an overlapping arrangement of its internal contractile proteins. Skeletal muscle is called **voluntary** because it is usually subject to conscious control. The other types of muscle are **involuntary** (not usually under conscious control), and they're never attached to bones.

A typical skeletal muscle cell is about 100 μm in diameter and 3 cm (30,000 μm) long; some are as thick as 500 μm and as long as 30 cm, such as in the sartorius muscle that crosses the thigh from hip to knee. Because of their extraordinary length, skeletal muscle cells are usually called **muscle fibers** or **myofibers**.

A skeletal muscle is composed not only of muscular tissue, but also of fibrous connective tissue: the *endomysium* that surrounds each muscle fiber, the *perimysium* that bundles muscle fibers together into fascicles, and the *epimysium* that encloses the entire muscle (see fig. 10.1). These connective tissues are continuous with the collagen fibers of tendons and those, in turn, with the collagen of the bone matrix. Thus, when a muscle fiber contracts, it pulls on these collagen fibers and typically moves a bone.

Collagen is neither excitable nor contractile, but it is somewhat extensible and elastic. When a muscle lengthens, for example during extension of a joint, its collagenous components resist excessive stretching and protect the muscle from injury. When a muscle relaxes, elastic recoil of the collagen may help to return the muscle to its resting length and keep it from becoming too flaccid. Some authorities contend that recoil of the tendons and other collagenous tissues contributes significantly to the power output and efficiency of a muscle. When you are running, for example, recoil of the calcaneal tendon may help to lift the heel and produce some of the thrust as your toes push off from the ground. (Such recoil contributes significantly to the long, efficient leaps of a kangaroo.) Others feel that the elasticity of these components is negligible in humans and that the recoil is produced entirely by certain intracellular proteins of the muscle fibers themselves.

FIGURE 11.1 Skeletal Muscle Fibers. **APR**

? What tissue characteristics evident in this photo distinguish this from cardiac and smooth muscle?

Jose Luis Calvo/Shutterstock

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. Define *responsiveness*, *conductivity*, *contractility*, *extensibility*, and *elasticity*. State why each of these properties is necessary for muscle function.
2. How is skeletal muscle different from the other types of muscle?

11.2 Skeletal Muscle Cells

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the structural components of a muscle fiber;
- b. name the major proteins of a muscle fiber and state the function of each; and
- c. relate the striations of a muscle fiber to the overlapping arrangement of its protein filaments.

11.2a The Muscle Fiber

In order to understand muscle function, you must know how the organelles and macromolecules of a muscle fiber are arranged. Perhaps more than any other cell, a muscle fiber exemplifies the adage, *Form follows function*. It has a complex, tightly organized internal structure in which even the spatial arrangement of protein molecules is closely tied to its contractile function.

The plasma membrane of a muscle fiber is called the **sarcolemma**,¹ and its cytoplasm is called the **sarcoplasm**. The sarcoplasm is occupied mainly by long protein cords called **myofibrils** about 1 μm in diameter (fig. 11.2), which extend for the entire length of the cell. It also contains an abundance of **glycogen**, a starchlike carbohydrate that provides energy for the cell during heightened levels of exercise, and the red oxygen-binding pigment **myoglobin**, which provides some of the oxygen needed for muscular activity.

Most organelles of the cell, such as mitochondria, are packed into the spaces between the myofibrils. The smooth endoplasmic reticulum, here called the **sarcoplasmic reticulum (SR)**, forms a network around each myofibril like a mesh stocking around one's leg (the blue web in fig. 11.2). At regular intervals, it has dilated end sacs called **terminal cisterns**, which cross the muscle fiber from one side to the other. The sarcolemma has tubular infoldings called **transverse (T) tubules**, which penetrate through the cell and emerge on the other side. Each T tubule is closely associated with two terminal cisterns running alongside it, one on each side.

Muscle fibers have numerous sausage-shaped nuclei pressed against the inside of the sarcolemma. Mammalian muscle fibers have 30 to 80 nuclei per millimeter, so a typical 3 cm fiber may have 900 to 2,400 nuclei; the longest ones, as in the sartorius muscle, may have over 20,000 nuclei! Muscle fibers cannot undergo mitosis, and it is easy in this light to see why: It would be unimaginable to synchronize the mitotic activity of so many nuclei.

¹sarco = flesh, muscle; lemma = husk

FIGURE 11.2 Structure of a Skeletal Muscle Fiber. This is a single cell containing 11 myofibrils (9 shown at the left end and 2 cut off at midfiber). A few myofilaments are shown projecting from the myofibril at the left. Most muscle fibers have from several dozen to a thousand or more myofibrils. Myofibril fine structure is shown in figure 11.3.

? After reading a little farther in this chapter, explain why it is important for the transverse tubule to be so closely associated with the terminal cisterns.

These many nuclei are crucial to repair of the mild muscle fiber injuries routinely caused by physical exercise. Within a few hours of injury, motor proteins (dynein) carry nuclei along microtubules to sites of damage, where the nuclei aggregate. By genetic transcription and translation, new proteins are synthesized to repair the damage. Repair is impressively quick and efficient, being nearly complete within 24 hours.

The unusual multinuclear condition of skeletal muscle fibers results from their embryonic development. Several stem cells, called **myoblasts**,² fuse to produce each fiber, with each myoblast contributing one nucleus. Some myoblasts remain as adult stem cells called **satellite cells** between the muscle fiber and endomysium. These play an important role in muscle growth and in the repair of fiber injuries on a larger scale.

Muscle has a high demand for ATP and therefore possesses an exceptionally large number of mitochondria wedged in between the

myofibrils. Mitochondria near the sarcolemma have the typical bean shape seen in many other cells, but deep inside the muscle fiber, they form a more dynamic, ever-changing tubular network influenced by exercise. Muscle contraction also requires a lot of calcium ions (Ca^{2+}), as you will see, but this presents a problem. A high concentration of Ca^{2+} in the cytosol is lethal—it can react with phosphate ions to precipitate as calcium phosphate crystals, and can trigger cell death by apoptosis. Therefore, at rest, a muscle cell stores its Ca^{2+} in the sarcoplasmic reticulum, safely bound to a protein called **calsequestrin**.³ In a resting muscle fiber, Ca^{2+} is about 10,000 times as concentrated in the SR as it is in the cytosol. When the cell is stimulated, ion gates in the SR membrane open and Ca^{2+} floods into the cytosol to activate contraction. The T tubule signals the SR when to release these calcium bursts.

11.2b Myofilaments

Let's return to the myofibrils just mentioned—the long protein cords that fill most of the muscle cell—and look at their structure

²myo = muscle; blast = precursor

³cal = calcium; sequestr = to set apart or separate; in = protein

at a finer, molecular level. It's here that the key to muscle contraction lies. Each myofibril is a bundle of parallel proteins called **muscle filaments** or **myofilaments** (see the left end of fig. 11.2). There are three kinds of myofilaments:

1. **Thick filaments** (fig. 11.3a, b) are about 15 nm in diameter. Each is made of several hundred molecules of a motor protein called **myosin**. A myosin molecule is shaped like a golf club, with two chains intertwined to form a shaftlike *tail* and a double globular *head* projecting from it at an angle. A thick filament consists of a bundle of 200 to 500 myosin molecules with their heads directed outward in a helical array around the bundle. The heads on one half of the thick filament angle to the left, and the heads on the other half angle to the right; in the middle is a *bare zone* with no heads.
2. **Thin filaments** (fig. 11.3c, d), 7 nm in diameter, are composed primarily of two intertwined strands of a protein called **fibrous (F) actin**. Each F actin is like a bead necklace—a string of subunits called **globular (G) actin**. Each G actin has an **active site** that can bind to the head of a myosin molecule. A thin filament also has 40 to 60 molecules of yet another protein, **tropomyosin**. When a muscle fiber is relaxed, each tropomyosin blocks the active sites of six or seven G actins and prevents myosin from binding to them. Each tropomyosin molecule, in turn, has a smaller, two-part calcium-binding protein called **troponin** bound to it.
3. **Elastic filaments** (see figs. 11.4, 11.5b), 1 nm in diameter, are made of a huge springy protein called **titin**.⁴ They run through the core of each thick filament and anchor it to structures called the *Z disc* at one end and *M line* at the other. Titin stabilizes the thick filament, centers it between the thin filaments, prevents overstretching, and recoils like a spring after a muscle is stretched.

Myosin and actin are called **contractile proteins** because they do the work of shortening the muscle fiber. Tropomyosin and troponin are called **regulatory proteins** because, together, they act like a switch to determine when the fiber can contract and when it can't. Several clues as to how they do this may be apparent from what has already been said—calcium ions are released into the sarcoplasm to activate contraction; calcium binds to troponin; troponin is also bound to tropomyosin; and tropomyosin blocks the active sites of actin, so that myosin cannot bind to it when the muscle isn't stimulated. Perhaps you are already forming some idea of the contraction mechanism to be explained shortly.

At least seven other accessory proteins occur in the thick and thin filaments or are associated with them. Among other functions, they anchor the myofilaments, regulate their length, and keep them aligned with each other for optimal contractile effectiveness. The most clinically important of these is **dystrophin**, an enormous protein located between the sarcolemma and the outermost myofilaments. It links actin filaments to a peripheral protein on the inner face of the sarcolemma. Through a series of linking proteins (fig. 11.4), this leads ultimately to the fibrous endomysium surrounding the muscle fiber. Therefore, when the thin filaments

FIGURE 11.3 Molecular Structure of Thick and Thin Filaments. (a) A single myosin molecule composed of two intertwined proteins. (b) A thick filament composed of a bundle of myosin molecules. (c) A thin filament composed of actin, tropomyosin, and troponin. (d) A region of overlap between the thick and thin filaments.

move, dystrophin transfers the force to the basal lamina, endomysium, and ultimately to the tendon. Genetic defects in dystrophin are responsible for the disabling disease *muscular dystrophy* (see Deeper Insight 11.4).

⁴tit = giant; in = protein

FIGURE 11.4 Dystrophin. Dystrophin ultimately transfers the force of moving actin filaments to tissues leading to the tendon of a muscle.

11.2c Striations and Sarcomeres

Myosin and actin are not unique to muscle; they occur in nearly all cells, where they function in cellular motility, mitosis, and transport of intracellular materials. In skeletal and cardiac muscle they are especially abundant, however, and are organized in a precise array that accounts for the striations of these muscle types (**figs. 11.5, 11.3d**).

Striated muscle has dark **A bands** alternating with lighter **I bands**. (*A* stands for *anisotropic* and *I* for *isotropic*, which refer to the way these bands affect polarized light. To help remember which band is which, think “dArk” and “lIght.”) Each A band consists of thick filaments lying side by side. Part of the A band, where thick and thin filaments overlap, is especially dark. In this region, each thick filament is surrounded by a hexagonal array of thin filaments (**fig. 11.5c**). In the middle of the A band, there is a lighter region called the **H band**,⁵ into which the thin filaments don’t reach. In the middle of the H band, the thick filaments are linked to each other through a dark, transverse protein complex called the **M line**.⁶

I bands have the hexagonally arranged thin filaments, but no thick filaments (**fig. 11.5d**). Each light I band is bisected by a dark narrow **Z disc**⁷ (**Z line**), which provides anchorage for the thin and

⁵*H* = *helle* = bright (German)

⁶*M* = *Mittel* = middle (German)

⁷*Z* = *Zwischenscheibe* = between disc (German)

FIGURE 11.5 Muscle Striations and Their Molecular Basis. (a) Five myofibrils of a single muscle fiber, showing the striations in the relaxed state (TEM). (b) The overlapping pattern of thick and thin filaments that accounts for the striations seen in part (a). (c) Cross section of A band showing thick filaments surrounded by hexagonal arrays of thin filaments. (d) Cross section of I band, which has thin filaments only. **APR**

a: Don W. Fawcett/Science Source

TABLE 11.1 The Structural Hierarchy of a Skeletal Muscle	
Structural Level	Description
Muscle	 A contractile organ, usually attached to bones by way of tendons. Composed of bundles (fascicles) of tightly packed, long, parallel cells (muscle fibers). Supplied with nerves and blood vessels and enclosed in a fibrous epimysium that separates it from neighboring muscles.
Fascicle	 A bundle of muscle fibers within a muscle. Supplied by nerves and blood vessels and enclosed in a fibrous perimysium that separates it from neighboring fascicles.
Muscle Fiber	 A single muscle cell. Slender, elongated, threadlike, enclosed in a specialized plasma membrane (sarcolemma). Contains densely packed bundles (myofibrils) of contractile protein myofilaments, multiple nuclei immediately beneath the sarcolemma, and an extensive network of specialized smooth endoplasmic reticulum (sarcoplasmic reticulum). Enclosed in a thin fibrous sleeve called endomysium.
Myofibril	 A bundle of protein myofilaments within a muscle fiber; myofibrils collectively fill most of the cytoplasm. Each surrounded by sarcoplasmic reticulum and mitochondria. Has a banded (striated) appearance due to orderly overlap of protein myofilaments.
Sarcomere	 A segment of myofibril from one Z disc to the next in the fiber's striation pattern. Hundreds of sarcomeres end to end compose a myofibril. The functional, contractile unit of the muscle fiber.
Myofilaments	 Fibrous protein strands that carry out the contraction process. Includes thick myofilaments composed mainly of myosin, thin myofilaments composed mainly of actin, and elastic filaments composed of titin. Thick and thin myofilaments slide over each other to shorten each sarcomere. Shortening of end-to-end sarcomeres shortens the entire muscle.

elastic filaments. Each segment of a myofibril from one Z disc to the next is called a **sarcomere**⁸ (SAR-co-meer), the functional contractile unit of the muscle fiber. You can see in figure 11.1 that a muscle fiber consists of numerous end-to-end sarcomeres. Sarcomeres are about $2.5 \pm 1 \mu\text{m}$ long, so an average, 3 cm muscle fiber has about 12,000 sarcomeres, end to end. A muscle shortens because its individual sarcomeres shorten and pull the Z discs closer to each other, and dystrophin and the linking proteins pull on the extracellular proteins of the muscle. As the Z discs are pulled closer together, they pull on the sarcolemma to achieve overall shortening of the cell.

Table 11.1 reviews the organization of skeletal muscle at successive structural levels from the whole muscle to the myofilaments.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- What special terms are given to the plasma membrane, cytoplasm, and smooth ER of a muscle cell?
- What is the difference between a myofilament and a myofibril?
- List five proteins of the myofilaments and describe their physical arrangement.
- Sketch the overlapping pattern of myofilaments to show how they account for the A bands, I bands, H bands, and Z discs.

11.3 The Nerve–Muscle Relationship

Expected Learning Outcomes

When you have completed this section, you should be able to

- explain what a motor unit is and how it relates to muscle contraction;
- describe the structure of the junction where a nerve fiber (axon) meets a muscle fiber; and
- explain why a cell has an electrical charge difference across its plasma membrane and, in general terms, how this relates to muscle contraction.

Skeletal muscle cannot contract unless it is stimulated by a nerve (or with electrodes). If its nerve connections are severed or poisoned, a muscle is paralyzed. If the connection is not restored, the paralyzed muscle wastes away in a shrinkage called *denervation atrophy*. Thus, muscle contraction cannot be understood without first understanding the relationship between nerve and muscle cells.

11.3a Motor Neurons and Motor Units

Skeletal muscles are served by nerve cells called *somatic motor neurons*, whose cell bodies are in the brainstem and spinal cord. Their axons, called **somatic motor fibers**, lead to the muscles. Each nerve fiber branches out to multiple muscle fibers, but each muscle fiber is supplied by only one motor neuron.

When a nerve signal approaches the end of an axon, it spreads out over all of its terminal branches and stimulates all muscle

FIGURE 11.6 Motor Units.

(a) A slice of spinal cord depicting two motor neurons in its anterior horn. Some motor neurons (yellow) are small, relatively sensitive, and easily activated. Others (violet) are large, less sensitive, and activated only when greater muscular strength is needed. (b) In the muscle, the muscle fibers of small motor units are relatively small. Large motor units have larger and more numerous muscle fibers. Note that the muscle fibers of any given motor unit are distributed throughout the muscle and commingled with the fibers of other motor units (red), not clustered in one place.

fibers supplied by them. Thus, these muscle fibers contract in unison; there is no way to stimulate some but not all of them. Since they behave as a single functional unit, one nerve fiber and all the muscle fibers innervated by it are called a **motor unit** (fig. 11.6). One motor neuron typically supplies 200 or more muscle fibers distributed across as many as 100 fascicles. Therefore, when stimulated, these muscle fibers cause not merely a local twitch in one fascicle, but contraction over a wider area. Effective muscle contraction usually requires the activation of many motor units at once.

Motor units can be much smaller or larger than 200 muscle fibers to serve different purposes. Where fine control is needed, we have *small motor units*. These typically are supplied by small, relatively sensitive neurons, innervating relatively small muscle fibers. Where strength is more important than fine control, we have *large motor units*. These are innervated by less sensitive neurons with larger cell bodies, thicker axons, and thicker, more numerous muscle fibers. These motor units are activated when strength is needed for a demanding task.

Consider a hand or eye muscle that requires fine motor control. Here, 1,000 muscle fibers may be innervated by 200 to 300 motor neurons with small motor units of only 3 to 5 muscle fibers each. Turning a few motor units on or off produces small, subtle changes in muscle action. Then consider a powerful thigh or calf muscle such as the quadriceps femoris or gastrocnemius. Here, every 1,000 muscle fibers may be controlled by only 1 or 2 neurons with large motor units of 500 to 1,000 muscle fibers

⁸sarco = muscle; mere = part, segment

each. Turning a few motor units on or off produces relatively large changes in muscle action, with large increments in strength but little fine control or subtlety.

In addition to adjustments in strength and control, another advantage of having multiple motor units in each muscle is that they work in shifts. Muscle fibers fatigue when subjected to continual stimulation. If all the fibers in one of your postural muscles fatigued at once, for example, you could collapse. To prevent this, other motor units take over while the fatigued ones recover, and the muscle as a whole can sustain long-term contraction.

11.3b The Neuromuscular Junction

The point where a nerve fiber meets any target cell is called a **synapse** (SIN-aps). When the target cell is a muscle fiber, the synapse is also called a **neuromuscular junction (NMJ)** or **motor end plate** (fig. 11.7). Each terminal branch of the nerve fiber within the NMJ forms a separate synapse with the muscle fiber. The sarcolemma of the NMJ is indented, a little like a handprint pressed into soft clay. If you imagine the nerve fiber to be like your forearm, branching out at the end like your fingers, the individual synapses

FIGURE 11.7 Innervation of Skeletal Muscle. (a) Motor nerve ending on a muscle fiber. (b) Detail of the neuromuscular junction. (c) Light micrograph (LM) of neuromuscular junctions (compare the SEM photo on the opening page of this chapter).

would be like the dents where your fingertips press into the clay. Thus, one nerve fiber stimulates the muscle fiber at several nearby points within the NMJ.

At each synapse, the nerve fiber ends in a bulbous swelling called the **axon terminal**. The terminal doesn't directly touch the muscle fiber but is separated from it by a narrow space called the **synaptic cleft**, about 60 to 100 nm wide (scarcely wider than the thickness of one plasma membrane).

The axon terminal contains spheroidal organelles called **synaptic vesicles**, which are filled with a chemical, **acetylcholine (ACh)** (ASS-eh-till-CO-leen)—one of many *neurotransmitters* to be introduced in the next chapter. The electrical signal (nerve impulse) traveling down a nerve fiber cannot cross the synaptic cleft like a spark jumping between electrodes—rather, it causes the synaptic vesicles to undergo exocytosis, releasing ACh into the cleft. ACh thus functions as a chemical messenger from the nerve cell to the muscle cell.

To respond to ACh, each synapse has about 50 million **ACh receptors**—proteins incorporated in the sarcolemma across from the axon terminals. To maximize the number of ACh receptors and thus its sensitivity to the neurotransmitter, the sarcolemma in this area has infoldings about 1 μm deep, called **postsynaptic membrane folds (junctional folds)**, which increase the surface area of ACh-sensitive membrane. The muscle nuclei beneath the folds are specifically dedicated to the synthesis of ACh receptors and other proteins of the local sarcolemma. A deficiency of ACh receptors leads to muscle weakness in the disease *myasthenia gravis* (see Deeper Insight 11.4).

The entire NMJ is enclosed in a **basal lamina**, a mat of collagen and glycoprotein that separates the muscle fiber and nerve ending from the surrounding connective tissue. The basal lamina

also passes through the synaptic cleft and virtually fills it. Both the sarcolemma and that part of the basal lamina in the cleft contain **acetylcholinesterase (AChE)** (ASS-eh-till-CO-lin-ESS-ter-ase). This is an enzyme that breaks down ACh after the ACh has stimulated the muscle cell; thus, it is important in turning off muscle contraction and allowing the muscle to relax (see Deeper Insight 11.1).

11.3c Electrically Excitable Cells

Muscle and nerve cells are regarded as *electrically excitable cells* because their plasma membranes exhibit voltage changes in response to stimulation. The study of the electrical activity of cells, called **electrophysiology**, is a key to understanding nerve activity, muscle contraction, the heartbeat and electrocardiogram, and other physiological phenomena. The details of electrophysiology are presented in chapter 12, but a few fundamental principles must be introduced here so you can understand muscle excitation.

The electrical activity of cells hinges on differences in the concentration of ions in the intracellular fluid (ICF) and extracellular fluid (ECF) adjacent to the plasma membrane. The ICF contains a greater concentration of negative anions than the ECF does—especially negatively charged proteins, nucleic acids, and phosphates, which are trapped in the cell and give its interior a net negative charge. That is, the membrane is **polarized**, like a little battery. Furthermore, the ICF has a much higher concentration of potassium ions (K^+) than the ECF, whereas the ECF has a much higher concentration of sodium ions (Na^+). The electrical events that initiate muscle contraction are driven by the movements of these two cations through the membrane when a muscle or nerve cell is excited.

DEEPER INSIGHT 11.1

CLINICAL APPLICATION

Neuromuscular Toxins and Paralysis

Toxins that interfere with synaptic function can paralyze the muscles. Organophosphate pesticides such as malathion are *cholinesterase inhibitors* that bind to AChE and prevent it from degrading ACh. Depending on the dose, this can prolong the action of ACh and produce *spastic paralysis*, a state in which the muscles contract and cannot relax; clinically, this is called a *cholinergic crisis*. It poses a danger of suffocation if it affects the laryngeal and respiratory muscles. Another example of spastic paralysis is *tetanus (lockjaw)*, caused by the toxin of a soil bacterium, *Clostridium tetani*. In the spinal cord, a neurotransmitter called glycine normally stops motor neurons from producing unwanted muscle contractions. The tetanus toxin blocks glycine release and thus causes overstimulation and spastic paralysis of the muscles.

Flaccid paralysis is a state in which the muscles are limp and cannot contract. This too can cause respiratory arrest if it affects the thoracic muscles. Among the causes of flaccid paralysis are poisons such as curare (cue-RAH-ree), which competes with ACh for receptor sites but doesn't stimulate the muscle. Curare is extracted from certain plants

and used by some South American natives to poison blowgun darts. It has been used to treat muscle spasms in some neurological disorders and to relax abdominal muscles for surgery, but other muscle relaxants have now replaced curare for most purposes.

Another cause of flaccid paralysis is *botulism*, a type of food poisoning caused by a neuromuscular toxin secreted by the bacterium *Clostridium botulinum*. Botulinum toxin blocks ACh release. Purified botulinum toxin is marketed as Botox Cosmetic. It is injected in small doses into specific facial muscles. Wrinkles gradually disappear as muscle paralysis sets in over the next few hours. The effect lasts about 4 months until the muscles retighten and the wrinkles return. Botox treatment has become a fast-growing cosmetic medical procedure in the United States, as its usage has expanded to other conditions and many people go for cosmetic treatment every few months. It has had some undesirable consequences, however, as it is sometimes administered by unqualified practitioners. Even some qualified physicians use it for treatments not yet approved by the FDA, and some host festive “Botox parties” for treatment of patients in assembly-line fashion.

A difference in electrical charge from one point to another is called an *electrical potential*, or *voltage*. It typically measures 12 volts (V) for a car battery and 1.5 V for a flashlight battery, for example. On the sarcolemma of a muscle cell, the voltage is much smaller, about -90 millivolts (mV), but critically important to life. (The negative sign refers to the relatively negative charge on the intracellular side of the membrane.) This voltage is called the **resting membrane potential (RMP)**. It is maintained by the sodium–potassium pump, as explained in section 12.4b.

When a nerve or muscle cell is stimulated, dramatic things happen electrically, as we shall soon see in the excitation of muscle. Ion channels in the plasma membrane open and Na^+ instantly flows into the cell, driven both by its concentration difference across the membrane and by its attraction to the negative charge of the cell interior—that is, it flows down an **electrochemical gradient**. These Na^+ cations override the negative charge just inside the membrane, so the inside of the membrane briefly becomes positive. This is called **depolarization** of the membrane. Immediately, Na^+ channels close and K^+ channels open. K^+ rushes out of the cell, partly because it is repelled by the positive sodium charge and partly because it is more concentrated in the ICF than in the ECF—that is, it flows down its own electrochemical gradient in the direction opposite from the sodium movement. The loss of K^+ ions from the cell turns the inside of the membrane negative again (**repolarization**). This quick up-and-down voltage shift, from the negative RMP to a positive value and then back to the RMP again, is called an **action potential**. The RMP is a stable voltage seen in a “waiting” cell, whereas the action potential is a quickly fluctuating voltage seen in an active, stimulated cell.

Action potentials have a way of perpetuating themselves—an action potential at one point on a plasma membrane causes another one to happen immediately in front of it, which triggers another one a little farther along, and so forth. A wave of action potentials spreading along a nerve fiber like this is called a *nerve impulse* or *nerve signal*. Such signals also travel along the sarcolemma of a muscle fiber. Resting and action potentials are more fully explained in chapter 12. Here, we will next examine how they lead to muscle contraction.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- What differences would you expect to see between a motor unit where muscular strength is more important than fine control and another motor unit where fine control is more important?
- State the functions of the axon terminal and its synaptic vesicles.
- Distinguish between acetylcholine, an acetylcholine receptor, and acetylcholinesterase. State where each is found and describe the function it serves.
- What accounts for the resting membrane potential seen in unstimulated nerve and muscle cells?
- What is the difference between a resting membrane potential and an action potential?

11.4 Behavior of Skeletal Muscle Fibers

Expected Learning Outcomes

When you have completed this section, you should be able to

- explain how a nerve fiber stimulates a skeletal muscle fiber;
- explain how stimulation of a muscle fiber activates its contractile mechanism;
- explain the mechanism of muscle contraction;
- explain how a muscle fiber relaxes; and
- explain why the force of a muscle contraction depends on the muscle’s length prior to stimulation.

The process of muscle contraction and relaxation has four major phases: (1) excitation, (2) excitation–contraction coupling, (3) contraction, and (4) relaxation. Each phase occurs in several smaller steps, which we now examine in detail.

11.4a Excitation

Excitation is the process in which action potentials in the motor nerve fiber lead to action potentials in the muscle fiber. The steps in excitation are shown in **figure 11.8**. Follow the figure carefully as you read the following description to ensure understanding of the process.

- A nerve signal arrives at the axon terminal and opens voltage-gated calcium channels. Calcium ions enter the terminal.
- Calcium stimulates the synaptic vesicles to release acetylcholine (ACh) into the synaptic cleft. One action potential causes exocytosis of about 60 vesicles, and each vesicle releases about 10,000 molecules of ACh.
- ACh diffuses across the synaptic cleft and binds to receptors on the sarcolemma.
- These receptors are ligand-gated ion channels. Two ACh molecules must bind to each receptor to open the channel. When it opens, Na^+ flows quickly into the cell while K^+ slowly flows out. The voltage on the sarcolemma quickly rises to a less negative value as Na^+ enters the cell, then falls back to the RMP when the channels close. This rapid up-and-down fluctuation in voltage at the motor end plate is called the **end-plate potential (EPP)**.
- Areas of sarcolemma next to the end plate have voltage-gated ion channels that open in response to the EPP. Some of these are specific for Na^+ and admit it to the cell, while others are specific for K^+ and allow it to leave. These ion movements create an *action potential*. The muscle fiber is now excited.

FIGURE 11.8 Excitation of a Muscle Fiber. These events link action potentials in a motor nerve fiber to the generation of action potentials in the muscle fiber. See the corresponding numbered steps in the text for explanation.

11.4b Excitation–Contraction Coupling

Excitation–contraction coupling refers to events that link action potentials on the sarcolemma to activation of the myofilaments, thereby preparing them to contract. The steps in the coupling process are shown in **figure 11.9**.

- 6 A wave of action potentials spreads from the motor end plate in all directions, like ripples on a pond. When this wave of excitation reaches the T tubules, it continues down them into the cell interior.
- 7 Action potentials open voltage-gated ion channels in the T tubules. These are linked to calcium channels in the terminal cisterns of the sarcoplasmic reticulum (SR). Thus, channels in the SR open as well and calcium diffuses out of the SR, down its concentration gradient into the cytosol.
- 8 Calcium binds to the troponin of the thin filaments.
- 9 The troponin–tropomyosin complex changes shape and exposes the active sites on the actin. This makes them available for binding to myosin heads.

11.4c Contraction

Contraction is the step in which the muscle fiber develops tension and may shorten. The mechanism of contraction is called the **sliding filament theory**. It holds that the myofilaments don't become any shorter during contraction; rather, the thin filaments slide over the thick ones and pull the Z discs behind them, causing each sarcomere as a whole to shorten. The individual steps in this mechanism are shown in **figure 11.10**.

- 10 The myosin head must have an ATP molecule bound to it to initiate contraction. **Myosin ATPase**, an enzyme in the head, hydrolyzes this ATP into ADP and phosphate (P_i). The energy released by this process activates the head, which “cocks” into an extended, high-energy position. The head temporarily keeps the ADP and P_i bound to it.
- 11 The cocked myosin binds to an exposed active site on the thin filament, forming a **cross-bridge** between the myosin and actin.
- 12 Myosin releases the ADP and P_i and flexes into a bent, low-energy position, tugging the thin filament along with it. This is called the **power stroke**. The head remains bound to actin until it binds a new ATP.
- 13 The binding of a new ATP to myosin destabilizes the myosin–actin bond, breaking the cross-bridge. The myosin head now undergoes a **recovery stroke**. It hydrolyzes the new ATP, recocks (returns to step 10), and attaches to a new active site farther down the thin filament, ready for another power stroke.

It may seem as if releasing the thin filament at step 13 would simply allow it to slide back to its previous position, so nothing would have been accomplished. Think of the sliding filament mechanism, however, as being similar to the way you would pull in a boat anchor hand over hand. When the myosin head cocks, it is like

your hand reaching out to grasp the anchor rope. When it flexes back into the low-energy position, it is like your elbow flexing to pull on the rope and draw the anchor up a little bit. When you let go of the rope with one hand, you hold onto it with the other one, alternating hands until the anchor is pulled in. Similarly, when one myosin head releases actin in preparation for the recovery stroke, there are many other heads on the same thick filament holding onto the thin filament so it doesn't slide back. At any given moment during contraction, about half of the heads are bound to the thin filament and the other half are extending forward to grasp it farther down. That is, the myosin heads don't all stroke at once but contract sequentially.

Each head acts in a jerky manner, but hundreds of them working together produce a smooth, steady pull on the thin filament. This is similar to the locomotion of a millipede—a wormlike animal with a few hundred tiny legs. Watch an online video of a crawling millipede and you will see that each leg takes individual jerky steps, but all the legs working together produce a smooth gliding movement, like the glide of a thick muscle filament walking along a thin one. Note that even though the muscle fiber contracts, the *myofilaments don't become shorter* any more than a rope becomes shorter as you pull in an anchor.

A single cycle of power and recovery strokes by all myosin heads in a muscle fiber would shorten the fiber about 1%. A fiber, however, may shorten by as much as 40% of its resting length, so obviously the cycle of power and recovery must be repeated many times by each myosin head. Each head carries out about five strokes per second, and each stroke consumes one ATP.

11.4d Relaxation

When the nerve fiber stops stimulating it, a muscle fiber relaxes and returns to its resting length. This is achieved by the steps shown in **figure 11.11**.

- 14 Nerve signals stop arriving at the neuromuscular junction, so the axon terminal stops releasing ACh.
- 15 As ACh dissociates (separates) from its receptor, AChE breaks it down into fragments that cannot stimulate the muscle. The axon terminal reabsorbs these fragments for recycling. All of this happens continually while the muscle is stimulated, too, but when nerve signals stop, no more ACh is released to replace that which breaks down. Therefore, stimulation of the muscle fiber by ACh ceases.
- 16 From excitation through contraction, the SR simultaneously releases and reabsorbs Ca^{2+} ; but when the nerve fiber stops firing and excitation ceases, Ca^{2+} release also ceases and only its reabsorption continues.
- 17 Owing to reabsorption by the SR, the level of free calcium in the cytosol falls dramatically. When calcium dissociates from troponin, it's not replaced.
- 18 Tropomyosin moves back into the position where it blocks the active sites of the actin filament. Myosin can no longer bind to actin, and the muscle fiber ceases to produce or maintain tension.

FIGURE 11.9 Excitation–Contraction Coupling. These events link action potentials in the muscle fiber to the release and binding of calcium ions. See the corresponding numbered steps in the text for explanation. The numbers in this figure begin where figure 11.8 ended.

FIGURE 11.10 The Sliding Filament Mechanism of Contraction. This is a cycle of repetitive events that cause a thin filament to slide over a thick filament and generate tension in the muscle. See the corresponding numbered steps in the text for explanation. The numbers in this figure begin where figure 11.9 ended. Lower left: diagram of a contracting sarcomere.

FIGURE 11.11 Relaxation of a Muscle Fiber. These events lead from the cessation of a nerve signal to the release of thin filaments by myosin. See the corresponding numbered steps in the text for explanation. The numbers in this figure begin where figure 11.10 ended.

Relaxation alone doesn't return a muscle to its resting length. That must be achieved by some force pulling the muscle and stretching it. For example, if the biceps flexes the elbow and then relaxes, it stretches back to its resting length only if the elbow is extended by contraction of the triceps or by the pull of gravity on the forearm.

▶▶▶ APPLY WHAT YOU KNOW

One of the most important properties of proteins is their ability to change shape repeatedly (see section 2.4e). Identify at least two muscle proteins that must change shape in order for a muscle to contract and relax.

11.4e The Length–Tension Relationship and Muscle Tone

The tension generated by a muscle, and therefore the force of its contraction, depends on how stretched or contracted it was at the outset. This principle is called the **length–tension relationship**. The reasons for it can be seen in **figure 11.12**. If a fiber was already extremely contracted, its thick filaments would be rather close to the Z discs, as on the left side of the figure. The fiber couldn't contract much farther before the thick filaments would butt against the Z discs and stop. The contraction would be brief and weak. On the other hand, if a muscle fiber was extremely stretched, as on the right, there would be little overlap between the thick and thin filaments. The myosin heads would be unable to get a grip on the thin filaments, and again the contraction would be weak.

FIGURE 11.12 The Length–Tension Relationship.

DEEPER INSIGHT 11.2

CLINICAL APPLICATION

Rigor Mortis

*Rigor mortis*⁹ is the hardening of the muscles and stiffening of the body that begins 3 to 4 hours after death. It occurs partly because the deteriorating sarcoplasmic reticulum releases calcium into the cytosol, and the deteriorating sarcolemma admits more calcium from the extracellular fluid. The calcium activates myosin–actin cross-bridging. Once bound to actin, myosin can't release it without first binding an ATP molecule, and of course no ATP is available in a dead body. Thus, the thick and thin filaments remain rigidly cross-linked until the myofilaments begin to decay. Rigor mortis peaks about 12 hours after death and then diminishes over the next 48 to 60 hours.

Between these extremes, there is an optimum resting length at which a muscle responds with the greatest force. In this range (the flat top of the curve), the sarcomeres are 2.0 to 2.25 μm long. If the sarcomeres are less than 60% or more than 175% of their optimal length, they develop no tension at all in response to a stimulus.

The complete length–tension curve is derived from muscles isolated from an animal (often the frog gastrocnemius muscle) for laboratory stimulation. In reality, a muscle *in situ* (in its natural position in the living body) is never as extremely stretched or contracted as the far right and left sides of the figure depict. For one thing, the attachments of muscles to the bones and limitations on bone movement restrict muscle contraction to the midrange of the curve. For another, the central nervous system continually monitors and adjusts the length of the resting muscles, maintaining a state of partial contraction called **muscle tone**. This maintains optimum sarcomere length and makes the muscles ideally ready for action. The elastic filaments of the sarcomere also help to maintain enough myofilament overlap to ensure effective contraction when the muscle is called into action.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- What change does ACh cause in an ACh receptor? How does this electrically affect the muscle fiber?
- How do troponin and tropomyosin regulate the interaction between myosin and actin?
- Describe the roles played by ATP in the power and recovery strokes of myosin.
- What steps are necessary for a contracted muscle to return to its resting length?

⁹*rigor* = rigidity; *mortis* = of death

11.5 Behavior of Whole Muscles

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the stages of a muscle twitch;
- explain how successive muscle twitches can add up to produce stronger muscle contractions;
- distinguish between isometric and isotonic contraction; and
- distinguish between concentric and eccentric contraction.

Now you know how an individual muscle cell shortens. Our next objective is to move up to the organ grade of structure and consider how this relates to the action of the muscle as a whole.

11.5a Muscle Twitches

When a muscle is directly stimulated with an electrode, it exhibits a quick cycle of contraction and relaxation called a **muscle twitch**. **Figure 11.13** is a graph of a twitch, called a **myogram**, showing the three phases of the response. The red line represents the amount of tension in the muscle.

At the left, we see that when a muscle is first stimulated, it doesn't respond immediately. There is a delay, typically about 2 milliseconds (ms) long, called the **latent period**. This is the time required for excitation, excitation–contraction coupling, and tensing the elastic components within the muscle. The force generated during the latent period is called **internal tension**. It isn't visible on the myogram because it causes no shortening of the muscle.

Once the elastic components are taut, the muscle begins to produce **external tension** and move a resisting object, or load, such as a bone or body limb. This is the **contraction phase** of the twitch. By analogy, imagine lifting a weight suspended from a rubber band. At first, internal tension would only stretch the rubber band. Then, as the rubber band became taut, external tension would lift the weight.

FIGURE 11.13 Idealized Myogram of a Muscle Twitch.

? What role does ATP play during the relaxation phase?

DEEPER INSIGHT 11.3 MEDICAL HISTORY

Galvani, Volta, and Animal Electricity

The invention of modern dry cells can be traced to studies of frog muscle by Italian anatomist Luigi Galvani (1737–98). He suspended isolated frog legs from a copper hook and noticed that they twitched when touched with an iron scalpel. He attributed this to “animal electricity” in the legs. The physicist Alessandro Volta (1745–1827) investigated Galvani's discovery further. He concluded that when two different metals (such as the copper hook and iron scalpel) are separated by an electrolyte solution (a frog's tissue fluids), a chemical reaction occurs that produces an electrical current. This current had stimulated the muscle in the legs of Galvani's frogs and caused the twitch. Based on this principle, Volta invented the first simple voltaic cell, the forerunner of today's dry cells and automobile batteries. The frog gastrocnemius muscle and its attached sciatic nerve, typically removed from the body and attached to laboratory stimulating and recording equipment, have remained a popular preparation for muscle research and teaching muscle physiology for centuries since Galvani's and Volta's time, even today.

The contraction phase is short-lived because the sarcoplasmic reticulum begins to quickly reabsorb Ca^{2+} even before the muscle develops maximal force. As the Ca^{2+} level falls, myosin releases the thin filaments and muscle tension declines. This brings about the **relaxation phase** seen in the myogram. As shown by the asymmetry of the myogram, the muscle contracts more quickly than it relaxes. The entire twitch lasts from about 7 to 100 ms, so a muscle could theoretically complete about 10 to 140 twitches per second (if only the math mattered).

11.5b Stimulus Intensity and Contraction Strength

It's obvious from our everyday experience that a muscle doesn't always contract with the same strength; contraction strength must be proportional to the task at hand. That strength, as we shall now see, depends on stimulus intensity. In the artificial stimulation just described, there are two components of intensity—the *voltage* of each stimulus applied by the electrode, and the *frequency*, or number of stimuli per second.

These relationships of contraction strength to stimulus voltage and frequency can be demonstrated with the frog gastrocnemius–sciatic nerve preparation mentioned in Deeper Insight 11.3. They apply equally to a human muscle. First consider such a setup in which we stimulate the muscle directly with an electrode. A weak, low-voltage stimulus produces no response. If we increase the voltage little by little and stimulate each time, we eventually find a minimum voltage that elicits a muscle twitch; this voltage is called the **threshold**. Raising the voltage still higher, with other conditions held constant, produces twitches no stronger than those at threshold. Superficially, the muscle seems to give its maximum response once the stimulus intensity is at threshold or higher.

However, even for a constant voltage, twitches can vary in strength under natural conditions. This is so for a variety of reasons:

- Twitch strength depends on how stretched the muscle was just before it was stimulated, as we have just seen in the length–tension relationship.
- Twitches become weaker as a muscle fatigues, as discussed later in this chapter.
- Twitches vary with the temperature of the muscle; a warmed-up muscle contracts more strongly because enzymes such as the myosin heads work more quickly.
- Twitch strength varies with the muscle's state of hydration, which affects the spacing between thick and thin filaments and therefore the ability to form myosin–actin cross-bridges.
- Twitch strength varies with stimulus frequency; stimuli arriving close together produce stronger twitches than stimuli arriving at longer time intervals, as we will see shortly.

It shouldn't be surprising that twitches vary in strength. Indeed, an individual twitch isn't strong enough to do any useful work. Muscles must contract with variable strength for different tasks, such as lifting a glass of champagne compared with lifting barbells at a gym.

In their normal anatomical setting, of course, muscles aren't stimulated by electrodes; they're stimulated by nerves. Using the frog gastrocnemius–sciatic preparation, suppose we now stimulate the nerve with our electrode and let the nerve stimulate the muscle. Again, if we start at low voltage, we get no reaction, like stimuli 1 and 2 at the top of **figure 11.14**. At threshold (stimulus 3), we get a weak twitch (shown at the bottom). If we continue to raise the voltage, we see stronger twitches, up to a point (stimuli 4 to 7).

That seems to contradict what we obtained when stimulating the muscle directly. The reason is that higher voltages excite more and more nerve fibers in the motor nerve (middle row of the figure), and thus stimulate more and more motor units to contract. The process of bringing more motor units into play is called **recruitment** or **multiple motor unit (MMU) summation**.

This is seen not only in artificial stimulation; it's part of the way the nervous system behaves naturally to produce varying muscle contractions. The neuromuscular system behaves according to the **size principle**—smaller, less powerful motor units with smaller, slower nerve fibers are activated first. This is sufficient for delicate tasks and refined movements, but if more power is needed, then larger motor units with larger, faster nerve fibers are subsequently activated.

But even when stimulus intensity (voltage) remains constant, twitch strength can vary with stimulus frequency. High-frequency stimulation produces stronger twitches than low-frequency stimulation. In **figure 11.15a**, we see that when a muscle is stimulated at low frequency, say 5 to 10 stimuli/s, it produces an identical twitch for each stimulus and fully recovers between twitches.

At higher stimulus frequencies, say 20 to 40 stimuli/s, each new stimulus arrives before the previous twitch is over. Each new twitch “rides piggyback” on the previous one and generates higher tension (**fig. 11.15b**). This phenomenon goes by two names: **temporal¹⁰ summation**, because it results from two stimuli arriving close

FIGURE 11.14 The Relationship Between Stimulus Intensity (Voltage) and Muscle Tension. Top row: Nine stimuli of increasing strengths. The first two are subthreshold stimuli. Middle row: Cross section of a motor nerve with seven nerve fibers. The colored nerve fibers are the excited ones; note that none are excited by the subthreshold stimuli above. Bottom row: Graph of muscle tension. Subthreshold stimuli (1–2) produce no muscle contraction. When stimuli reach or exceed threshold (3–7), they excite more and more nerve fibers and motor units; thus, they produce stronger and stronger contractions. This is multiple motor unit summation (recruitment). Once all of the nerve fibers are stimulated (7–9), further increases in stimulus strength produce no further increase in muscle tension.

together in time, or **wave summation**, because it results from one wave of contraction added to another. Wave upon wave, each twitch reaches a higher level of tension than the one before, and the muscle relaxes only partially between stimuli. This effect produces a state of sustained fluttering contraction called **incomplete tetanus**.

In the laboratory, an isolated muscle can be stimulated at such high frequency that the twitches fuse into a single, nonfluctuating contraction called **complete (fused) tetanus** (**fig. 11.15c**). This doesn't happen in the body, however, because motor neurons don't fire that fast. Indeed, there is an inhibitory mechanism in the spinal cord that prevents them from doing so. Complete tetanus is injurious to muscle and associated soft tissues, so spinal inhibition protects the muscles by preventing complete tetanus. Muscle tetanus should not be confused with the disease of the same name caused by the tetanus toxin (see Deeper Insight 11.1).

Despite the fluttering contraction seen in incomplete tetanus, we know that a muscle taken as a whole can contract very smoothly. This is possible because motor units function asynchronously; when one motor unit relaxes, another contracts and takes over so that the muscle doesn't lose tension.

¹⁰tempor = time; al = pertaining to

FIGURE 11.15 The Relationship Between Stimulus Frequency and Muscle Tension. (a) Twitch. At an unnaturally low stimulus frequency, as in laboratory preparations, the muscle relaxes completely between stimuli and shows twitches of uniform strength. (b) At a stimulus frequency within normal physiological range, the muscle doesn't have time to relax completely between twitches and the force of each twitch builds on the previous one, creating the state of incomplete tetanus. In this state, a muscle can attain three to four times as much tension, or force, as a single twitch produces. (c) At an unnaturally high stimulus frequency, attained only in laboratory preparations, the muscle can't relax at all between twitches, and twitches fuse into a state of complete tetanus.

FIGURE 11.16 Isometric and Isotonic Contraction. (a) Isometric contraction, in which a muscle develops tension but doesn't shorten. (b) Isotonic concentric contraction, in which the muscle shortens while maintaining a constant degree of tension. (c) Isotonic eccentric contraction, in which the muscle maintains tension while it lengthens, allowing a muscle to relax without going suddenly limp.

? Name a muscle that undergoes eccentric contraction as you sit down in a chair.

11.5c Isometric and Isotonic Contraction

In muscle physiology, “contraction” doesn't always mean the shortening of a muscle—it may mean only that the muscle produces internal tension while an external resistance causes it to stay

the same length or even become longer. Thus, physiologists speak of different kinds of muscle contraction as *isometric* versus *isotonic* and *concentric* versus *eccentric* (fig. 11.16).

Suppose you lift a heavy dumbbell. When you first contract the muscles of your arm, you can feel the tension building in

them even though the dumbbell isn't yet moving. At this point, your muscles are contracting at a cellular level, but their tension is absorbed by the elastic components and is resisted by the weight of the load; the muscle as a whole doesn't shorten or produce any external movement. This phase is called **isometric**¹¹ **contraction**—contraction without a change in length (fig. 11.16a). This occurs at the beginning of any muscle contraction, but is prolonged in lifting weights. However, it isn't merely a prelude to movement. The isometric contraction of antagonistic muscles at a single joint is important in maintaining joint stability at rest, and the isometric contraction of postural muscles is what keeps us from sinking in a heap to the floor. **Isotonic**¹² **contraction**—contraction with a change in length but no change in tension—begins when internal tension builds to the point that it overcomes the resistance. The muscle now shortens, moves the load, and maintains essentially the same tension from then on (fig. 11.16b). Isometric and isotonic contraction are both phases of normal muscular action (fig. 11.17).

There are two forms of isotonic contraction: concentric and eccentric. In **concentric contraction**, a muscle shortens as it maintains tension—for example, when the biceps contracts and flexes the elbow. In **eccentric contraction**, a muscle lengthens as it maintains tension. If you set that dumbbell down again (fig. 11.16c), your biceps lengthens as you extend your elbow, but it maintains tension to act as a brake and keep you from simply dropping the weight. A weight lifter uses

concentric contraction when lifting a dumbbell and eccentric contraction when lowering it. When weight lifters suffer muscle injuries, it is usually during the eccentric phase, because the sarcomeres and connective tissues of the muscle are pulling in one direction while the weight is pulling the muscle in the opposite direction.

In summary, during isometric contraction, a muscle develops tension without changing length, and in isotonic contraction, it changes length while maintaining constant tension. In concentric contraction, a muscle maintains tension as it shortens, and in eccentric contraction, it maintains tension while it lengthens.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

16. State three or more reasons why muscle twitch strength can vary even when stimulus intensity remains constant.
17. Explain the role of tetanus in normal muscle action.
18. Describe an everyday activity not involving the arms in which your muscles would switch from isometric to isotonic contraction.
19. Describe an everyday activity not involving the arms that would involve concentric contraction and one that would involve eccentric contraction.

¹¹iso = same, uniform; metr = length; ic = pertaining to

¹²iso = same, uniform; ton = tension; ic = pertaining to

FIGURE 11.17 Isometric and Isotonic Phases of Contraction.

At the beginning of a contraction (isometric phase), muscle tension rises but the length remains constant (the muscle doesn't shorten). When tension overcomes the resistance of the load, the tension levels off and the muscle begins to shorten and move the load (isotonic phase).

? How would you extend this graph in order to show eccentric contraction?

11.6 Muscle Metabolism

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain how skeletal muscle meets its energy demands during rest and exercise;
- b. explain the basis of muscle fatigue and soreness;
- c. discuss why extra oxygen is needed even after an exercise has ended;
- d. distinguish between two physiological types of muscle fibers, and explain their functional roles;
- e. discuss the factors that affect muscular strength; and
- f. discuss the effects of resistance and endurance exercises on muscles.

11.6a ATP Sources

All muscle contraction depends on ATP; no other energy source can serve in its place. The supply of ATP depends, in turn, on the availability of oxygen and organic fuels such as glucose and fatty acids. To understand how muscle manages its ATP budget, you must be acquainted with the two main pathways of ATP synthesis: *anaerobic fermentation* and *aerobic respiration* (see fig. 2.31). Each of these has advantages and disadvantages. Anaerobic fermentation enables a cell to produce ATP without the need for oxygen, but the ATP yield is very limited and the process generates

FIGURE 11.18 Modes of ATP Synthesis During Exercise.

a toxic by-product, lactate (lactic acid), which must be removed from the muscle and disposed of by the liver. By contrast, aerobic respiration produces far more ATP and no lactate, but it requires a continual supply of oxygen. Although aerobic respiration is best known as a pathway for glucose oxidation, it is also used to extract energy from other organic compounds. In a resting muscle, most ATP is generated by the aerobic respiration of fatty acids.

During the course of exercise, different mechanisms of ATP synthesis are used depending on the exercise duration. We'll view these from the standpoint of immediate, short-term, and long-term energy, but muscle doesn't make sudden shifts from one mechanism to another like an automobile transmission shifting gears. Rather, these mechanisms blend and overlap as the exercise continues (**fig. 11.18**).

Immediate Energy

In a short, intense exercise such as a 100 m dash, the myoglobin in a muscle fiber supplies oxygen for a limited amount of aerobic respiration at the outset, but this oxygen supply is quickly depleted. Until the respiratory and cardiovascular systems catch up with the heightened oxygen demand, the muscle meets most of its ATP needs by borrowing phosphate groups (P_i) from other molecules and transferring them to ADP. Two enzyme systems control these phosphate transfers (**fig. 11.19**):

1. **Myokinase** (MY-oh-KY-nase) transfers P_i from one ADP to another, converting the latter to ATP that myosin can use.
2. **Creatine kinase** (CREE-uh-tin KY-nase) obtains P_i from a phosphate-storage molecule, **creatine phosphate (CP)**, and donates it to ADP to make ATP. This is a fast-acting system that helps to maintain the ATP level while other ATP-generating mechanisms are being activated.

ATP and CP, collectively called the **phosphagen system**, provide nearly all the energy used for short bursts of intense activity. Muscle contains about 5 millimoles of ATP and 15 millimoles of CP per kilogram of tissue. Perhaps surprisingly, at the outset of an intense exercise, the amount of ATP in the muscle fibers changes

very little, but the amount of CP drops rapidly. The total supply of ATP + CP is enough to power about 1 minute of brisk walking or 6 seconds of sprinting or fast swimming. The phosphagen system is especially important in activities requiring short bursts of maximal effort, such as football, baseball, and weight lifting.

FIGURE 11.19 The Phosphagen System. (a) Myokinase, which obtains phosphates from ADP. (b) Creatine kinase, which obtains phosphates from creatine phosphate.

Short-Term Energy

As the phosphagen system is exhausted, the muscles transition to anaerobic fermentation to generate ATP by glycolysis. The point at which this occurs is called the **anaerobic threshold**, or sometimes the **lactate threshold** because one can begin to detect a rise in blood lactate levels at this time. (Athletes in training can detect this with a handheld device that measures lactate in a single drop of blood from a pinprick.) During the anaerobic phase, the muscles obtain glucose from the blood and their own stored glycogen and metabolize it to lactate. As we have seen earlier (see fig. 2.31), this pathway, the **glycogen–lactate system**, generates a net yield of 2 ATP for each glucose consumed. (*Anaerobic fermentation* is its final step, the conversion of pyruvate to lactate.) It can produce enough ATP for 30 to 40 seconds of maximum activity. Playing basketball or running completely around a baseball diamond, for example, depends heavily on this energy-transfer system.

Long-Term Energy

After 40 seconds or so, the respiratory and cardiovascular systems “catch up” and deliver oxygen to the muscles fast enough for aerobic respiration to once again meet most of the ATP demand. Aerobic respiration produces much more ATP than glycolysis does—typically another 30 ATP per glucose. Thus it is a very efficient means of meeting the ATP demands of prolonged exercise. One’s rate of oxygen consumption rises for 3 to 4 minutes and then levels off at a *steady state* in which aerobic ATP production keeps pace with the demand. In exercises lasting more than 10 minutes, over 90% of the ATP is produced aerobically. For up to 30 minutes, the energy for this comes about equally from glucose and fatty acids; then, as glucose and glycogen are depleted, fatty acids become the more significant fuel.

11.6b Fatigue and Endurance

Muscle **fatigue** is the progressive weakness and loss of contractility that results from prolonged use of the muscles. For example, if you hold a heavy book at arm’s length for a minute, you will feel your muscles growing weaker and soon you’ll be unable to hold it up. Repeatedly squeezing a rubber ball, pushing a video game button, or trying to take lecture notes from a fast-talking professor produces fatigue in the hand muscles. In high-intensity, short-duration exercise, fatigue is thought to result from the following factors:

- **Potassium accumulation.** Each action potential releases K^+ from the sarcoplasm to the extracellular fluid. This lowers the membrane potential (hyperpolarizes the cell) and makes the muscle fiber less excitable. This is especially significant in the T tubules, where the low volume of ECF enables the K^+ concentration to rise to a high level and interfere with the release of calcium from the sarcoplasmic reticulum.
- **ADP/ P_i accumulation.** The hydrolysis of ATP generates an ever-growing pool of $ADP + P_i$. ADP slows the cross-bridge cycling mechanism of contraction. Free phosphate (P_i) inhibits calcium release from the sarcoplasmic reticulum, calcium sensitivity of the contractile mechanism, and force production by the myofibrils. It is now thought to be a major contributor to muscle fatigue.

In exercise of long duration but low intensity, fatigue may result partially from the preceding causes, but is predominantly due to the following:

- **Fuel depletion.** Declining levels of muscle glycogen and blood glucose leave less fuel for ATP synthesis. Long-distance runners and cyclists call this “hitting the wall,” and often endeavor to delay fatigue by means of high-carbohydrate diets before the race, loading the muscles with extra glycogen.
- **Electrolyte loss.** The loss of electrolytes through sweating can alter the ion balance of the extracellular fluid enough to reduce muscle excitability.
- **Central fatigue.** Exercising muscle generates ammonia, which is absorbed by the brain and inhibits motor neurons of the cerebrum. For this and other reasons not yet well understood, the central nervous system produces less signal output to the skeletal muscles. This is where psychological factors come into play, such as the will to complete a marathon.

Some former hypotheses on muscle fatigue have been discredited by more recent research. ATP depletion per se is no longer thought to cause fatigue; the ATP level in fatigued muscle is almost as great as in rested muscle. It was also long thought that the lactate from anaerobic fermentation contributed to fatigue by lowering the pH in the muscle fiber, altering the shapes of the contractile and regulatory proteins. Evidence has now shown, however, that lactate is removed to the liver about as fast as the muscles produce it, so it doesn’t accumulate in the muscle tissue and probably has little or nothing to do with fatigue.

The ability to maintain high-intensity exercise for more than 4 or 5 minutes is determined in large part by one’s **maximum oxygen uptake (VO_{2max})**—the point at which the rate of oxygen consumption reaches a plateau and increases no further with an added workload. VO_{2max} is proportional to body size; it peaks around age 20; it is usually greater in males than in females; and it can be twice as great in a trained endurance athlete as in an untrained person. A typical sedentary adult uses a maximum of about 35 milliliters of oxygen per minute per kilogram of body weight. Such a person weighing 73 kg (160 lb) and exercising at maximum intensity could therefore “burn” oxygen at about 2.6 L/min., which sets a limit to one’s rate of ATP production. Elite endurance athletes can have a VO_{2max} of about 70 mL/min./kg (5.2 L/min. for the same body weight).

11.6c Excess Postexercise Oxygen Consumption

You have probably noticed that you breathe heavily not only during strenuous exercise but also for several minutes afterward (fig. 11.18). This is to meet a metabolic demand called **excess postexercise oxygen consumption (EPOC)**, also known by an older popularized term, **oxygen debt**. EPOC is the difference between the elevated rate of oxygen consumption at the end of an exercise and the normal rate at rest. It occurs in part because oxygen is needed to regenerate ATP aerobically, and that ATP goes in part to regenerate creatine phosphate. A small amount of oxygen serves to reoxygenate the muscle myoglobin, and the liver consumes

oxygen in disposing of the lactate generated by exercise. In addition, exercise raises the body temperature and overall metabolic rate, which in itself consumes more oxygen.

ATP and CP are replenished in the early minutes of heaviest postexercise breathing, and oxygen consumption remains elevated for as much as an hour more as the liver uses it to oxidize lactate. EPOC can be as much as six times one’s basal oxygen consumption, indicating that anaerobic mechanisms of ATP production during exercise allow six times as much physical exertion as would have been possible without those mechanisms.

11.6d Physiological Classes of Muscle Fibers

Not all muscle fibers are alike or adapted for the same tasks. For example, the weight-bearing and postural muscles of the back and lower limbs react slowly to stimulation and take up to 100 ms to reach peak tension. By contrast, muscles that control eye and hand movements react quickly to stimulation and reach peak tension in as little as 7.5 ms. The predominant fibers that compose these muscles are therefore called *slow-twitch* and *fast-twitch* fibers, respectively. We can find reasons for their differences in response time by looking at their cellular structure and biochemistry (table 11.2). The different fiber types can be identified in tissue sections with special histochemical staining (fig. 11.20).

Slow-twitch fibers are also called **slow oxidative (SO)** or **type I fibers**. They are well adapted for endurance and fatigue

FIGURE 11.20 Skeletal Muscle Fiber Types. (FG, fast glycolytic fibers; SO, slow oxidative fibers; FO, fast oxidative fibers)
G W Willis/Getty Images

TABLE 11.2 Classification of Skeletal Muscle Fibers		
Property	Fiber Type	
	Slow-Twitch (Slow Oxidative)	Fast-Twitch (Fast Glycolytic)
Twitch duration	As long as 100 ms	As short as 7.5 ms
Motor unit size	Smaller	Larger
Motor neurons	Smaller, more excitable	Larger, less excitable
Motor unit strength	Weaker	Stronger
Relative diameter	Smaller	Larger
ATP synthesis	Aerobic	Anaerobic
Fatigue resistance	Good	Poor
ATP hydrolysis	Slow	Fast
Glycolysis	Moderate	Fast
Myoglobin content	Abundant	Low
Glycogen content	Low	Abundant
Mitochondria	Abundant and large	Fewer and smaller
Capillaries	Abundant	Fewer
Color	Redder	Whiter, paler
Representative muscles in which fiber type is predominant	Soleus Erector spinae Quadratus lumborum	Gastrocnemius Biceps brachii Muscles of eye movement

resistance, so they are particularly important in muscles that support the body and maintain posture, such as the erector spinae and quadratus lumborum of the back. Their fatigue resistance stems from their *oxidative* mode of ATP production—that is, aerobic respiration. Oxidative metabolism, of course, requires a liberal supply of oxygen and the means to use it efficiently. Therefore, these fibers are surrounded by a dense network of blood capillaries, they are rich in mitochondria, and they have a high concentration of myoglobin, the red pigment that facilitates diffusion of oxygen from the blood into the muscle fiber. Slow-twitch fibers are also relatively thin, which minimizes the distance that oxygen must diffuse to even the deepest mitochondria. The slowness of these muscles is due to a sarcoplasmic reticulum that is relatively slow to release and reabsorb calcium, and a form of myosin ATPase that is relatively slow in its ATP hydrolysis and cross-bridge cycling. The high myoglobin concentration of these fibers gives them a relatively bright red color, so they are also called **red fibers**.

Fast-twitch fibers are also called **fast glycolytic (FG)** or **type II fibers**. They are well adapted for quick responses, so they are particularly important in the aforesaid eye and hand muscles, and in large muscles such as the gastrocnemius and biceps brachii, which we employ in such actions as jumping and elbow flexion. Their quickness stems from an especially extensive sarcoplasmic reticulum with fast release and reabsorption of calcium, and a form of myosin with very quick ATP hydrolysis and cross-bridge cycling. For energy, they depend primarily on glycolysis and anaerobic fermentation, which produces ATP more quickly (yet less efficiently) than aerobic respiration. To support this, they contain a high concentration of glycogen. They also have a high concentration of creatine phosphate, which, you will

recall, aids in rapidly regenerating ATP. They have fewer mitochondria than slow-twitch fibers. Fast-twitch fibers are thicker than slow-twitch, because thick fibers are stronger and they have no need for especially rapid oxygen delivery to the deepest cytoplasm. Also, without need of such rapid oxygen uptake, they have less myoglobin. For this reason, fast-twitch fibers are relatively pale and are called **white fibers**. But the price paid for these fast-twitch mechanisms and anaerobic ATP production is that these fibers fatigue more easily, as you may know from writer’s cramp or doing rapid biceps curls.

Some authorities recognize two subtypes of FG fibers called types IIA and IIB. Type IIB is the common type just described, whereas IIA (**intermediate** or **fast oxidative [FO] fibers**) combine fast-twitch responses with aerobic fatigue-resistant metabolism. Type IIA fibers, however, are known mainly from other species of mammals and are relatively rare in humans except in some endurance-trained athletes.

Nearly all muscles are composed of both SO and FG fibers, but usually one type or the other predominates according to the functions of that muscle—quick motility and reflexes, or sustained weight-bearing tension. People with different types and levels of physical activity differ in the proportion of one fiber type to another even in the same muscle, such as the *quadriceps femoris* of the anterior thigh (**table 11.3**). It is thought that people are born with a genetic predisposition for a certain ratio of fiber types. Those who go into competitive sports discover the sports at which they can excel and gravitate toward those for which heredity has best equipped them. One person might be a “born sprinter” and another a “born marathoner.”

In humans, small motor units are composed of relatively small SO muscle fibers and supplied by small but easily excited motor neurons. These motor units are not as strong as large ones but produce more precise movements. Large motor units are composed of larger FG fibers; supplied by larger, less excitable neurons; and produce more power but less fine control. In the *size principle* discussed earlier (section 11.5b), the nervous system recruits small SO motor units first, then larger FG motor units only if more strength is needed for a particular task.

Muscles composed mainly of SO fibers are called *red muscles*, and those composed mainly of FG fibers are called *white muscles* because of the color difference stemming from their difference in myoglobin content. Anyone who eats chicken or turkey may be unwittingly

familiar with this distinction. The thighs are dark meat composed of SO fibers adapted to long periods of standing, and the breast is white meat composed of FG fibers adapted for short bursts of power when the birds take flight. Duck breast, however, is dark meat (red muscle) adapted for long-distance flight, because unlike chickens and turkeys, domestic ducks are descended from migratory ancestors.

We saw in chapter 10 that sometimes two or more muscles act across the same joint and seem to have the same function. We have already seen some reasons why such muscles are not as redundant as they seem. Another reason is that they may differ in the proportion of SO to FG fibers. For example, the gastrocnemius and soleus muscles of the calf both insert on the calcaneus, so they exert the same pull on the heel. The gastrocnemius, however, is a white, predominantly FG muscle adapted for quick, powerful movements such as jumping, whereas the soleus is a red, SO muscle that does most of the work in standing and in endurance exercises such as jogging and skiing.

11.6e Muscular Strength and Conditioning

We have far more muscular strength than we normally use. The gluteus maximus can generate 1,200 kg of tension, and all the muscles collectively can produce a total tension of 22,000 kg (nearly 25 tons). Indeed, the muscles can generate more tension than the bones and tendons can withstand—a fact that accounts for many injuries to the patellar and calcaneal tendons. Muscular strength depends on a variety of anatomical and physiological factors:

- **Muscle size.** The strength of a muscle depends primarily on its size; thicker muscles can form more myosin–actin cross-bridges and therefore generate more tension. A muscle can exert a tension of about 3 to 4 kg/cm² of cross-sectional area. This is why the larger muscles of weight lifters are also stronger than average.
- **Fascicle arrangement** (see fig. 10.2). Pennate muscles such as the rectus femoris are stronger than parallel muscles such as the sartorius, which in turn are stronger than circular muscles such as the orbicularis oculi.
- **Size of active motor units.** Large motor units produce stronger contractions than small ones.
- **Multiple motor unit summation.** When a stronger muscle contraction is desired, the nervous system activates more and larger motor units. Getting “psyched up” for athletic competition is partly a matter of multiple motor unit (MMU) summation.
- **Temporal summation.** Nerve impulses usually arrive at a muscle in a series of closely spaced action potentials. Because of the temporal summation described earlier, the greater the frequency of stimulation, the stronger the muscle contraction.
- **The length–tension relationship.** As noted earlier, a muscle resting at optimum length is prepared to contract more forcefully than a muscle that is excessively contracted or stretched. This is affected by one’s posture, such as a runner’s crouch, just before the onset of muscular effort.

TABLE 11.3 Proportion of Slow Oxidative (SO) and Fast Glycolytic (FG) Fibers in the Quadriceps Femoris Muscle of Male Athletes		
Sample Population	SO	FG
Marathon runners	82%	18%
Swimmers	74	26
Average males	45	55
Sprinters and jumpers	37	63

- **Fatigue.** Rested muscles contract more strongly than fatigued ones.

As fitness trainers and exercise enthusiasts know, there are two kinds of exercise with different effects on muscles—resistance and endurance exercise. **Resistance exercise**, such as weight lifting, is the contraction of muscles against a load that resists movement. A few minutes of resistance exercise at a time, a few times each week, is enough to stimulate muscle growth. Growth results primarily from cellular enlargement, not cellular division. The muscle fibers synthesize more myofilaments and the myofibrils grow thicker. Myofibrils split longitudinally when they reach a certain size, so a well-conditioned muscle has more myofibrils than a poorly conditioned one. Muscle fibers themselves are incapable of mitosis, but there is some evidence that as they enlarge, they too may split longitudinally. A small part of muscle growth may therefore result from an increase in the number of fibers, but most of it results from the enlargement of fibers that have existed since puberty.

Endurance (aerobic) exercise, such as jogging or swimming, improves the fatigue resistance of the muscles by enhancing the delivery and use of oxygen. Slow-twitch fibers, especially, produce more mitochondria and glycogen and acquire a greater density of blood capillaries as a result of conditioning. Endurance exercise also improves skeletal strength; increases the red blood cell count and the oxygen transport capacity of the blood; and enhances the function of the cardiovascular, respiratory, and nervous systems.

Endurance training doesn't significantly increase muscular strength, and resistance training doesn't improve endurance. Optimal performance and musculoskeletal health require **cross-training**, which incorporates elements of both types. If muscles aren't kept sufficiently active, they become *deconditioned*—weaker and more easily fatigued.

▶▶▶ APPLY WHAT YOU KNOW

Is a weight lifter's muscle growth mainly the result of hypertrophy or hyperplasia?

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

20. From which two molecules can ADP borrow a phosphate group to become ATP? What is the enzyme that catalyzes each transfer?
21. In a long period of intense exercise, why does muscle generate ATP anaerobically at first and then switch to aerobic respiration?
22. List four causes of muscle fatigue.
23. List three causes of excess postexercise oxygen consumption.
24. What properties of fast glycolytic and slow oxidative fibers adapt them for different physiological purposes?

11.7 Cardiac and Smooth Muscle

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the structural and physiological differences between cardiac muscle and skeletal muscle;
- b. explain why these differences are important to cardiac function;
- c. describe the structural and physiological differences between smooth muscle and skeletal muscle; and
- d. relate the unique properties of smooth muscle to its locations and functions.

Cardiac and smooth muscle have special structural and physiological properties in common with each other, but different from those of skeletal muscle (**table 11.4**). These are related to their distinctive functions.

Any of the three types of muscle cells can be called **myocytes**. This term is preferable to *muscle fiber* for smooth and cardiac muscle because these two types don't have the long fibrous shape of skeletal muscle cells. They are relatively short, and in further contrast to skeletal muscle fibers, they have only one or two nuclei. Cardiac muscle cells are also called **cardiomyocytes**.

Cardiac and smooth muscle are *involuntary* muscle tissues, not usually subject to our conscious control. They receive no innervation from somatic motor neurons, but cardiac muscle and some smooth muscle receive nerves from the sympathetic and parasympathetic divisions of the autonomic nervous system (see chapter 15).

11.7a Cardiac Muscle

Cardiac muscle is limited to the heart, where its function is to pump blood. Knowing that, we can predict the properties it must have: (1) It must contract with a regular rhythm; (2) it must function in sleep and wakefulness, without fail or need of conscious attention; (3) it must be highly resistant to fatigue; (4) the cardiomyocytes of a given heart chamber must contract in unison so the chamber can effectively expel blood; and (5) each contraction must last long enough to expel blood. These functional necessities are the key to understanding how cardiac muscle differs structurally and physiologically from skeletal muscle (**table 11.4**).

Cardiac muscle is striated like skeletal muscle, but cardiomyocytes are shorter and thicker. They have one or two nuclei near the middle of the cell. Each cell is enclosed in an endomysium, but there is no perimysium or epimysium as in skeletal muscle. Cardiomyocytes branch slightly so each is joined end to end with several others. These intercellular connections, called **intercalated discs** (in-TUR-kuh-LAY-ted), appear as thick dark lines in stained tissue sections. An intercalated disc has electrical *gap junctions*

TABLE 11.4 Comparison of Skeletal, Cardiac, and Smooth Muscle			
Feature	Skeletal Muscle	Cardiac Muscle	Smooth Muscle
Location	Associated with skeletal system	Heart	Walls of viscera and blood vessels, iris of eye, arrector muscle of hair follicles
Cell shape	Long threadlike fibers	Short, slightly branched cells	Short fusiform cells
Cell length	100 μm–30 cm	50–120 μm	30–200 μm
Cell width	10–500 μm	10–20 μm	5–10 μm
Striations	Present	Present	Absent
Nuclei	Multiple nuclei, adjacent to sarcolemma	Usually one nucleus, near middle of cell	One nucleus, near middle of cell
Connective tissues	Endomysium, perimysium, epimysium	Endomysium only	Endomysium only
Sarcoplasmic reticulum	Abundant	Present	Scanty
T tubules	Present, narrow	Present, wide	Absent
Gap junctions	Absent	Present in intercalated discs	Present in unitary smooth muscle
Autorhythmicity	Absent	Present	Present in unitary smooth muscle
Thin filament attachment	Z discs	Z discs	Dense bodies
Regulatory proteins	Tropomyosin, troponin	Tropomyosin, troponin	Calmodulin, myosin light-chain kinase
Ca ²⁺ source	Sarcoplasmic reticulum	Sarcoplasmic reticulum and extracellular fluid	Mainly extracellular fluid
Ca ²⁺ receptor	Troponin of thin filament	Troponin of thin filament	Calmodulin of thick filament
Innervation and control	Somatic motor fibers (voluntary)	Autonomic fibers (involuntary)	Autonomic fibers (involuntary)
Nervous stimulation required?	Yes	No	No
Effect of nervous stimulation	Excitatory only	Excitatory or inhibitory	Excitatory or inhibitory
Mode of tissue repair	Limited regeneration, mostly fibrosis	Limited regeneration, mostly fibrosis	Relatively good capacity for regeneration

that allow each cardiomyocyte to directly stimulate its neighbors, and mechanical junctions that keep the cardiomyocytes from pulling apart when the heart contracts. The sarcoplasmic reticulum is less developed than in skeletal muscle, but the T tubules are larger and admit Ca²⁺ from the extracellular fluid. Damaged cardiac muscle is repaired by fibrosis. It has no satellite cells, and even though limited mitosis has been detected in cardiomyocytes following heart attacks, it doesn't produce a significant amount of regenerated functional muscle.

Unlike skeletal muscle, cardiac muscle can contract without the need of nervous stimulation. The heart has a built-in **pacemaker** that rhythmically sets off a wave of electrical excitation, which travels through the muscle and triggers the contraction of the heart chambers. The heart is said to be **autorhythmic**¹³ because of this ability to contract rhythmically and independently. Stimulation by the

autonomic nervous system, however, can increase or decrease the heart rate and contraction strength. Cardiac muscle doesn't exhibit quick twitches like skeletal muscle. Rather, it maintains tension for about 200 to 250 ms, giving the heart time to expel blood.

Cardiac muscle uses aerobic respiration almost exclusively. It is very rich in myoglobin and glycogen, and it has especially large mitochondria that fill about 25% of the cell, compared with smaller mitochondria occupying about 2% of a skeletal muscle fiber. Cardiac muscle is very adaptable with respect to the fuel used, but very vulnerable to interruptions in oxygen supply. Because it makes little use of anaerobic fermentation, cardiac muscle is highly resistant to fatigue.

11.7b Smooth Muscle **APR**

Smooth muscle is named for the fact that it has no striations, for a reason to be described shortly. Its myocytes are relatively small, allowing for fine control of such tissues and organs as a single

¹³auto = self

hair, the iris of the eye, and the tiniest arteries; yet, in the pregnant uterus, the myocytes become quite large and contribute to the powerful contractions of childbirth.

Smooth muscle isn't always innervated, but when it is, the nerve supply is autonomic, like that of the heart. Autonomic nerve fibers usually don't form precisely localized neuromuscular junctions with the myocytes. Rather, a nerve fiber has as many as 20,000 swellings called **varicosities** along its length (**fig. 11.21**). Each varicosity contains synaptic vesicles from which it releases neurotransmitters—usually norepinephrine from the sympathetic fibers and acetylcholine from the parasympathetic fibers. The myocyte has no motor end plate, but instead has receptors for these neurotransmitters distributed over its surface.

Whether innervated or not, smooth muscle responds to a wide variety of stimuli and often without any electrical excitation of the sarcolemma. It is much slower than skeletal and cardiac muscle to contract and relax, but it can remain contracted for a long time without fatigue and with minimal energy expenditure.

Smooth muscle doesn't usually form organs in itself, but forms layers in the walls of larger organs such as the stomach, intestines, uterus, and urinary bladder. In such cases, the muscle layer is quite variable in complexity. It can consist of as little as one cell in small arteries. The esophagus and intestines have an outer layer of longitudinal smooth muscle adjacent to a deeper, inner layer of circular muscle (**fig. 11.22**). When the longitudinal layer contracts, it shortens and dilates the organ; when the circular layer contracts, it constricts and lengthens the organ. In the stomach, urinary bladder, and uterus, smooth muscle forms

FIGURE 11.21 Varicosities of an Autonomic Nerve Fiber in Unitary Smooth Muscle.

FIGURE 11.22 Layers of Visceral Muscle in a Cross Section of the Esophagus.

three or more layers with bundles of myocytes running in multiple directions.

Smooth muscle can propel the contents of an organ, such as driving food through the digestive tract, voiding urine and feces, and expelling the infant in childbirth. By dilating or constricting the blood vessels and airway, it can modify the speed of air and blood flow, maintain blood pressure, and reroute blood from one pathway to another.

Unlike skeletal and cardiac muscle, smooth muscle is capable of not only hypertrophy (cellular growth) but also mitosis and hyperplasia (cell division). Thus, an organ such as the pregnant uterus grows by the addition of new myocytes as well as enlargement of existing ones. Injured smooth muscle regenerates well by mitosis.

Myocyte Structure

Smooth muscle myocytes have a fusiform shape, typically about 5 to 10 μm wide at the middle, tapering to a point at each end, and usually ranging from 30 to 200 μm long—but up to 500 μm in the pregnant uterus. They are enclosed in endomysium but have no perimysium, fascicles, or epimysium. There is only one nucleus, located near the middle of the cell. The sarcoplasmic reticulum is scanty and there are no T tubules. Thick and thin filaments are present, but there are no striations, sarcomeres, or myofibrils because the myofilaments aren't bundled and aligned with each other the way they are in striated muscle. Z discs are absent. In

their place are protein plaques called **dense bodies**, some adhering to the inner face of the plasma membrane and others dispersed throughout the sarcoplasm (see fig. 11.24). The membrane-associated dense bodies of one cell are often directly across from those of another, with linkages between them so that contractile force can be transmitted from cell to cell. Associated with the dense bodies is an extensive cytoskeletal network of intermediate filaments. Actin filaments attach to the intermediate filaments as well as directly to the dense bodies, so their movement (powered by myosin) is transferred to the sarcolemma and shortens the cell.

Types of Smooth Muscle

Smooth muscle tissue shows a range of types between two extremes called *multiunit* and *unitary* types (fig. 11.23). **Multiunit smooth muscle** occurs in some of the largest arteries and pulmonary air passages, arrector muscles of the hair follicles, and eye muscles that control the iris and lens. Its innervation, although autonomic, is to some degree similar to that of skeletal

muscle—the terminal branches of a nerve fiber synapse with individual myocytes and form a motor unit. Each varicosity is associated with a particular myocyte, and each myocyte responds independently of all the others—hence the name *multiunit*. Multiunit smooth muscle does not, however, generate action potentials. It contracts in response to variable (graded) electrical changes in the sarcolemma or even in the absence of electrical excitation.

Unitary (single-unit) smooth muscle is more common. It occurs in most blood vessels and in the digestive, respiratory, urinary, and reproductive tracts—therefore, it is also called **visceral muscle**. This type forms the aforementioned layers in many of the hollow viscera. The names *unitary* and *single-unit* refer to the fact that the myocytes of this type of muscle are electrically coupled to each other by gap junctions. This allows them to directly stimulate each other, so numerous cells contract as a unit, almost as if they were a single cell. In this muscle type, no nerve varicosity is associated with a specific myocyte. The varicosities simply release a flood of neurotransmitter into the tissue. Each nerve fiber can therefore stimulate multiple myocytes at once, and each myocyte can respond to more than one nerve fiber.

Excitation of Smooth Muscle

Whereas skeletal muscle contracts only in response to excitatory stimulation by a somatic motor fiber, smooth muscle can be stimulated in a multitude of ways. Some stimuli excite the myocyte and others inhibit it. Some produce action potentials in the sarcolemma, particularly in unitary smooth muscle, whereas others stimulate the myocyte by nonelectrical means. Some smooth muscle has no nerve supply at all. Modes of smooth muscle stimulation and some examples include

- **Autonomic nerve fibers and neurotransmitters.** For example, parasympathetic nerves secrete acetylcholine and stimulate gastrointestinal motility; sympathetic nerves secrete norepinephrine and dilate the bronchioles of the lungs.
- **Chemicals.** Smooth muscle reacts to hormones, carbon dioxide, oxygen, nitric oxide, low pH, and other chemical stimuli. The hormone oxytocin, for example, stimulates the labor contractions of the uterus, and histamine relaxes the smooth muscle of arteries.
- **Temperature.** Cold induces contraction of smooth muscle resulting in erection of the hairs and tautening of the skin in such regions as the areola and scrotum, whereas warmth relaxes smooth muscle in arteries of the skin.
- **Stretch.** The stomach and urinary bladder contract when stretched by food or urine.
- **Authorhythmicity.** Some unitary smooth muscle is autorhythmic, especially in the stomach and intestines. Some myocytes spontaneously depolarize at regular time intervals and set off waves of contraction throughout an entire layer of muscle. The rhythm is much slower than in cardiac muscle.

FIGURE 11.23 Multiunit and Unitary Smooth Muscle.

(a) Multiunit smooth muscle, in which each muscle cell receives its own nerve supply and contracts independently. (b) Unitary smooth muscle, in which a nerve fiber passes through the tissue without synapsing with any specific muscle cell, and muscle cells are coupled by electrical gap junctions.

Regardless of how a myocyte is stimulated, however, the immediate trigger for contraction is the same as in skeletal and cardiac muscle—calcium ions. In some cases, the Ca^{2+} comes from the sarcoplasmic reticulum (SR), as it does in skeletal muscle. With a relatively sparse SR, however, smooth muscle usually gets most of its Ca^{2+} from the extracellular fluid by way of gated calcium channels in the sarcolemma. Compensating for the paucity of SR, the sarcolemma has numerous little pockets called **caveolae** (CAV-ee-OH-lee) where its calcium channels are concentrated. Calcium is 10,000 times as concentrated in the ECF as in the cytosol, so if these channels are opened, it diffuses quickly into the cell. Because smooth muscle cells are relatively small, the incoming Ca^{2+} quickly reaches all of the myofilaments.

What opens these gated channels? Some are mechanically gated and open in response to physical distortion such as stretch. This is the case in organs that periodically fill and empty, such as the stomach and urinary bladder. Some are voltage-gated and open in response to electrical depolarization of the sarcolemma. Still others are ligand-gated and open in response to chemicals originating outside the cell or from the cytosol. Acetylcholine and norepinephrine, for example, bind to surface receptors and activate the formation of second messengers within the smooth muscle cell. This leads to a series of intracellular events that open the surface calcium channels from within.

▶▶▶ APPLY WHAT YOU KNOW

How is smooth muscle contraction affected by the drugs called calcium channel blockers? (See Deeper Insight 3.1.)

Contraction and Relaxation

Calcium ions are the immediate trigger for contraction, but unlike skeletal and cardiac muscle, smooth muscle has no troponin to bind it. Calcium binds instead to a similar protein called **calmodulin**¹⁴ (cal-MOD-you-lin), associated with myosin. Calmodulin then activates an enzyme called **myosin light-chain kinase**, which adds a phosphate group to a small regulatory protein on the myosin head. This activates the myosin ATPase, enabling it to bind to actin and hydrolyze ATP. The myosin then produces repetitive power and recovery strokes like those of skeletal muscle.

As thick filaments pull on the thin ones, the thin filaments pull on the dense bodies and membrane plaques. Through the dense bodies and cytoskeleton, force is transferred to the plasma membrane and the entire cell shortens. When a smooth muscle cell contracts, it puckers and twists somewhat like wringing out a wet towel (**fig. 11.24**).

In skeletal muscle, there is typically a 2 ms latent period between stimulation and the onset of contraction. In smooth muscle, by contrast, the latent period is 50 to 100 ms long. Tension peaks about 500 ms (0.5 second) after the stimulus and then declines over

FIGURE 11.24 Smooth Muscle Contraction. (a) Relaxed cells. (b) Contracted cells.

a period of 1 to 2 seconds. The effect of all this is that compared with skeletal muscle, smooth muscle is very slow to contract and relax. It is slow to contract because its myosin ATPase is a slow enzyme. It is slow to relax because the pumps that remove Ca^{2+} from the cytosol are also slow. As the Ca^{2+} level falls, myosin releases its phosphate group and is no longer able to hydrolyze ATP and execute power strokes. However, it doesn't necessarily detach from actin immediately. It has a **latch-bridge mechanism** that enables it to remain attached to actin for a prolonged time without consuming more ATP.

Smooth muscle often exhibits tetanus and is very resistant to fatigue. It makes most of its ATP aerobically, but its ATP requirement is small and it has relatively few mitochondria. Skeletal muscle requires 10 to 300 times as much ATP as smooth muscle to maintain the same amount of tension. The fatigue resistance and latch-bridge mechanism of smooth muscle are important in enabling it to maintain a state of continual tonic contraction called **smooth muscle tone**. Muscle tone keeps the arteries in a state of partial constriction called *vasomotor tone*. A widespread loss of muscle tone in the arteries can cause a dangerous drop in blood pressure. Smooth muscle tone also keeps the intestines partially contracted. The intestines are much

¹⁴acronym for *calcium modulating protein*

TABLE 11.5 Some Disorders of the Muscular System	
Contracture	Abnormal muscle shortening not caused by nervous stimulation. Can result from failure of the calcium pump to remove Ca^{2+} from the sarcoplasm or from contraction of scar tissue, as in burn patients.
Cramps	Painful muscle spasms caused by rapid firing of motor neurons; triggered by heavy exercise, cold, dehydration, electrolyte loss, low blood glucose, or lack of blood flow.
Crush syndrome	A shocklike state following the massive crushing of muscles; associated with high and potentially fatal fever, cardiac irregularities resulting from K^+ released from the muscle, and kidney failure resulting from blockage of the renal tubules with myoglobin released by the traumatized muscle. Myoglobinuria (myoglobin in the urine) is a common sign.
Delayed-onset muscle soreness	Pain, stiffness, and tenderness felt from several hours to a day after strenuous exercise. Associated with microtrauma to the muscles; with disrupted Z discs, myofibrils, and plasma membranes; and with elevated levels of myoglobin, creatine kinase, and lactate dehydrogenase in the blood.
Disuse atrophy	Reduction in the size of muscle fibers as a result of nerve damage or muscular inactivity, for example in limbs in a cast and in patients confined to a bed or wheelchair. Muscle strength can be lost at a rate of 3% per day of bed rest.
Fibromyalgia	Chronic pain of unknown cause, seeming to come from the muscles and bones but actually arising from abnormal processing of pain signals by the brain. Occurring twice as often in women as in men, especially between ages 30 and 50.
Myositis	Muscle inflammation and weakness resulting from infection or autoimmune disease.
You can find other muscle disorders described in the following places:	
Compartment syndrome in Deeper Insight 10.1; back injuries in Deeper Insight 10.2; hernia in Deeper Insight 10.3; common athletic injuries in Deeper Insight 10.9; paralysis in Deeper Insights 11.1 and 13.5; and muscular dystrophy and myasthenia gravis in Deeper Insight 11.4.	

longer in a cadaver than they are in a living person because of the loss of muscle tone at death.

Response to Stretch

Stretch alone sometimes causes smooth muscle to contract by opening mechanically gated calcium channels in the sarcolemma. Distension of the esophagus with food or the colon with feces, for example, evokes a wave of contraction called **peristalsis** (PERR-ih-STAL-sis) that propels the contents along the organ.

Smooth muscle exhibits a reaction called the **stress-relaxation** (or **receptive-relaxation**) **response**. When stretched, it briefly contracts and resists, but then relaxes. The significance of this response is apparent in the urinary bladder. If the stretched bladder contracted and didn't soon relax, it would expel urine almost as soon as it began to fill, thus failing to store the urine until an opportune time.

Remember that skeletal muscle can't contract very forcefully if it's overstretched. Smooth muscle, however, is less limited by the length-tension relationship. It contracts forcefully even when greatly stretched, so hollow organs such as the stomach and bladder can fill and then expel their contents efficiently. Skeletal muscle must be within 30% of optimum length in order to contract strongly when stimulated. Smooth muscle, by contrast, can be anywhere from half to twice its resting length and still contract powerfully. There are three reasons for this: (1) There are no Z discs, so thick filaments can't butt against them and stop the contraction; (2) since the thick and thin filaments

are not arranged in orderly sarcomeres, stretching of the muscle doesn't cause a situation in which there is too little overlap for cross-bridges to form; and (3) the thick filaments of smooth muscle have myosin heads along their entire length (there is no bare zone), so cross-bridges can form anywhere, not just at the ends. Smooth muscle also exhibits **plasticity**—the ability to adjust its tension to the degree of stretch. Thus, a hollow organ such as the bladder can be greatly stretched yet not become flabby when it is empty.

The muscular system suffers fewer diseases than any other organ system, but several of its more common dysfunctions are listed in **table 11.5**. The effects of aging on the muscular system are described in chapter 29.

BEFORE YOU GO ON

- Answer the following questions to test your understanding of the preceding section:
- 25. Explain why intercalated discs are important to cardiac muscle function.
 - 26. Explain why it is important for cardiac muscle to have longer-lasting contractions than skeletal muscle.
 - 27. How do unitary and multiunit smooth muscle differ in innervation and contractile behavior?
 - 28. How does smooth muscle differ from skeletal muscle with respect to its source of calcium and its calcium receptor?
 - 29. Explain why the stress-relaxation response is an important factor in smooth muscle function.

DEEPER INSIGHT 11.4

CLINICAL APPLICATION

Muscular Dystrophy and Myasthenia Gravis

Muscular dystrophy¹⁵ (MD) is a collective term for several hereditary diseases in which the muscles degenerate, weaken, and are gradually replaced by fat and fibrous scar tissue. The most common form of the disease is *Duchenne*¹⁶ *muscular dystrophy* (DMD), a sex-linked recessive trait affecting about 1 out of every 3,500 live-born males.

DMD is not evident at birth, but signs begin to appear around age 2 or 3, as a child shows difficulty keeping up with other children, falls frequently, and finds it hard to stand again. On average, it is diagnosed around age 5. It affects the muscles of the hips first; then the legs; and then progresses to the abdominal, spinal, and respiratory muscles as well as cardiac muscle. The muscles shorten as they atrophy, causing postural abnormalities such as scoliosis. About 90% of persons with DMD are wheelchair-dependent by the age of 15. Few live beyond the age of 30, but some survive and achieve much in their lives even into the 50s. For obscure reasons, persons with DMD also frequently suffer a progressive decline in mental ability. Death usually results from respiratory insufficiency, pulmonary infection, or heart failure. DMD is incurable, but is treated with exercise to slow the atrophy of the muscles and with braces to reinforce the weakened hips and maintain posture.

The underlying cause of DMD is a mutation in the gene for the muscle protein dystrophin (see fig. 11.4)—a large gene highly vulnerable to mutation. Without dystrophin, there is no coupling between the thin myofilaments and the sarcolemma. The sarcomeres move independently of the sarcolemma, creating tears in the membrane. The torn membrane admits excess Ca^{2+} into the cell, which activates intracellular proteases (protein-digesting enzymes). These enzymes degrade the contractile proteins of the muscle, leading to weakness and cellular necrosis. Dying muscle fibers are replaced with scar tissue, which blocks blood circulation in the muscle and thereby contributes to still further necrosis. Muscle degeneration accelerates in a fatal spiral of positive feedback.

Genetic screening can identify heterozygous carriers of DMD, allowing for counseling of prospective parents on the risk of having a child with the disease. However, about one out of three cases arises by a new spontaneous mutation and therefore cannot be predicted by genetic testing.

Myasthenia gravis¹⁷ (MG) (MY-ass-THEE-nee-uh GRAV-is) usually occurs in women between the ages of 20 and 40. It is an autoimmune disease in which antibodies attack the neuromuscular junctions and bind ACh receptors together in clusters. The muscle fiber then removes the clusters from the sarcolemma by endocytosis. As a result, the muscle fibers become less and less sensitive to ACh. The effects often appear first in the facial muscles and commonly include drooping eyelids (*ptosis*, fig. 11.25) and double vision (due to *strabismus*, inability to fixate on the same point with both eyes). The initial symptoms are often followed by difficulty in swallowing, weakness of the limbs, and poor physical endurance. Some people with MG die quickly as a result of respiratory failure, but others have normal life spans. One method of assessing the progress of the disease is to use *bungarotoxin*, a protein from cobra venom that binds to ACh receptors. The amount that binds is proportional to the number of receptors that are still functional. The muscle of an MG patient sometimes binds less than one-third as much bungarotoxin as normal muscle does.

Myasthenia gravis is often treated with cholinesterase inhibitors. These drugs retard the breakdown of ACh in the neuromuscular junction and enable it to stimulate the muscle longer. Immunosuppressive agents such as prednisone and azathioprine (Imuran) may be used to suppress the production of the antibodies that destroy ACh receptors. Since certain immune cells are stimulated by hormones from the thymus, removal of the thymus (*thymectomy*) helps to dampen the overactive immune response that causes myasthenia gravis. Also, a technique called *plasmapheresis* may be used to remove harmful antibodies from the blood plasma.

¹⁵ *dys* = bad, abnormal; *trophy* = growth

¹⁶ Guillaume B. A. Duchenne (1806–75), French physician

¹⁷ *my* = muscle; *asthen* = weakness; *grav* = severe

FIGURE 11.25 Test of Myasthenia Gravis. The subject is told to gaze upward. Within 60 to 90 seconds, there is obvious sagging (ptosis) of one eyelid due to inability to sustain stimulation of the orbicularis oculi muscle.

SYSTEM CONNECTIONS

Effects of the **MUSCULAR SYSTEM** on Other Organ Systems

INTEGUMENTARY SYSTEM

Facial expressions result from the action of muscles on the skin.

LYMPHOID AND IMMUNE SYSTEMS

Muscle contractions aid flow of lymph; exercise elevates levels of immune cells and antibodies in circulation; excessive exercise can inhibit immunity.

SKELETAL SYSTEM

Muscles move and stabilize joints and produce stresses that affect ossification, bone remodeling, and the shapes of bones.

NERVOUS SYSTEM

Muscles give expression to thoughts, emotions, and motor commands that arise in the central nervous system.

ENDOCRINE SYSTEM

Skeletal muscles provide protective cover for some endocrine glands; muscle mass affects insulin sensitivity.

CIRCULATORY SYSTEM

Muscle contractions affect blood flow in many veins; exercise stimulates growth of new blood vessels.

RESPIRATORY SYSTEM

Muscle contractions ventilate the lungs; muscles of the larynx and pharynx regulate airflow and speech; CO₂ generated by muscular activity stimulates respiration; abdominal muscles produce pressure bursts of coughing and sneezing and aid in deep breathing.

URINARY SYSTEM

A skeletal muscle sphincter retains urine in bladder until convenient for release; abdominal and pelvic muscles aid in compressing and emptying bladder; muscles of pelvic floor support bladder; bulbospongiosus muscle helps clear urine from male urethra.

DIGESTIVE SYSTEM

Muscles enable chewing and swallowing; muscles control voluntary aspect of defecation; abdominal muscles produce vomiting; abdominal and lumbar muscles protect digestive organs; muscles secrete hormones that stimulate liver metabolism and regulate glucose and lipid balance.

REPRODUCTIVE SYSTEM

Muscles are involved in sexual responses including erection and ejaculation; abdominal and pelvic muscles aid in childbirth.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

11.1 Types and Characteristics of Muscular Tissue

1. Five physiological properties of all muscular tissue and their relevance to muscle function
2. Distinguishing characteristics of skeletal muscle
3. Average and extreme sizes of skeletal muscle fibers
4. Connective tissues associated with a muscle fiber and their relationship to muscle–bone attachments

11.2 Skeletal Muscle Cells

1. The sarcolemma and sarcoplasm, and the roles of glycogen and myoglobin in the sarcoplasm
2. The role of myoblasts in the development of a muscle fiber, and how they give rise to the multinuclear condition of the muscle fiber and to the satellite cells external to the fiber
3. Structure and function of the sarcoplasmic reticulum and transverse tubules
4. Types of myofilaments that constitute a myofibril
5. Composition and molecular organization of a thick filament, and the structure of a myosin molecule
6. Composition of a thin filament; the organization of its actin, tropomyosin, and troponin; and the active sites of its actin monomers
7. Composition of elastic filaments and their relationship to the thick filaments and Z discs
8. The position and function of dystrophin in the muscle fiber
9. Names of the striations of skeletal and cardiac muscle and how they relate to the overlapping arrangement of thick and thin filaments
10. The definition of *sarcomere*

11.3 The Nerve–Muscle Relationship

1. Motor units; the meanings of *large* and *small motor units*; and the respective advantages of the two types
2. Structure of a neuromuscular junction and function of each of its components
3. The source, role, and fate of acetylcholine (ACh) in the neuromuscular junction

4. The role of acetylcholinesterase in neuromuscular function
5. How a nerve or muscle cell generates a resting membrane potential (RMP); the typical voltage of this potential in a skeletal muscle fiber
6. How an action potential differs from the RMP, and the effects of an action potential on a nerve or muscle cell

11.4 Behavior of Skeletal Muscle Fibers

1. Excitation of a muscle fiber; how a nerve signal leads to a traveling wave of electrical excitation in a muscle fiber
2. Excitation–contraction coupling; how electrical excitation of a muscle fiber leads to exposure of the active sites on the actin of a thin myofilament
3. The sliding filament mechanism of contraction; how exposure of the active sites leads to repetitive binding of myosin to actin and sliding of the thin filaments over the thick filaments
4. Muscle relaxation; how the cessation of the nerve signal leads to blockage of the active sites so myosin can no longer bind to them and maintain muscle tension
5. The roles of calcium, troponin, tropomyosin, and ATP in these processes
6. The length–tension relationship in muscle; why muscle would contract weakly if it was overcontracted or overstretched just prior to stimulation; and how this principle relates to the function of muscle tone

11.5 Behavior of Whole Muscles

1. Terms for the minimum stimulus intensity needed to make a muscle contract, and for the delay between stimulation and contraction
2. The phases of a muscle twitch
3. Reasons why muscle twitches vary in strength (tension)
4. How recruitment and tetanus are produced and how they affect muscle tension
5. Differences between isometric and isotonic contraction, and between the concentric and eccentric forms of isotonic contraction

11.6 Muscle Metabolism

1. Why a muscle cannot contract without ATP
2. Differences between aerobic respiration and anaerobic fermentation with respect to muscle function

3. The use of myoglobin and aerobic respiration to generate ATP at the outset of exercise
4. Two ways in which the phosphagen system generates ATP for continued exercise
5. How anaerobic fermentation generates ATP after the phosphagen system is depleted
6. Why a muscle is able to switch back to aerobic respiration to generate ATP after 40 seconds or so of exercise
7. Causes of muscle fatigue
8. VO_2max , why it partially determines one's ability to maintain high-intensity exercise, and why it differs from one person to another
9. Why exercise is followed by a prolonged state of elevated oxygen consumption, and the name of that state
10. Differences between slow oxidative and fast glycolytic muscle fibers; the respective advantages of each; how they relate to the power and recruitment of motor units; and examples of muscles in which each type predominates
11. Factors that determine the strength of a muscle
12. Examples of resistance exercise and endurance exercise, and the effects of each on muscle performance

11.7 Cardiac and Smooth Muscle

1. Reasons why cardiac muscle must differ physiologically from skeletal muscle
2. Structural differences between cardiomyocytes and skeletal muscle fibers
3. The autorhythmicity of the heart and its ability to contract without nervous stimulation
4. The unusual fatigue resistance of cardiac muscle; structural and biochemical properties that account for it
5. Functional differences between smooth muscle and the two forms of striated muscle
6. How the innervation of smooth muscle differs from that of skeletal muscle
7. Variations in the complexity and anatomical organization of smooth muscle
8. Various functions of smooth muscle
9. Two modes of smooth muscle growth
10. The structure of smooth muscle cells and what takes the place of the absent Z discs and T tubules
11. Differences between multiunit and unitary smooth muscle, and the nerve–muscle relationship of each

STUDY GUIDE

12. Various modes of stimulation of smooth muscle
13. How excitation–contraction coupling in smooth muscle differs from that in skeletal muscle; the roles of calmodulin and myo-

- sin light-chain kinase in smooth muscle contraction
14. The nature and effect of the latch-bridge mechanism in smooth muscle

15. The role of smooth muscle in peristalsis
16. Benefits of the stress–relaxation response of smooth muscle, and of its absence of a length–tension relationship

▶ Testing Your Recall

Answers in Appendix A

1. To make a muscle contract more strongly, the nervous system can activate more motor units. This process is called
 - a. recruitment.
 - b. summation.
 - c. incomplete tetanus.
 - d. twitch.
 - e. concentric contraction.
2. The functional unit of a muscle fiber is the _____, a segment from one Z disc to the next.
 - a. myofibril
 - b. I band
 - c. sarcomere
 - d. neuromuscular junction
 - e. striation
3. Before a skeletal muscle fiber can contract, ATP must bind to
 - a. a Z disc.
 - b. the myosin head.
 - c. tropomyosin.
 - d. troponin.
 - e. actin.
4. Before a skeletal muscle fiber can contract, Ca^{2+} must bind to
 - a. calsequestrin.
 - b. calmodulin.
 - c. the myosin head.
 - d. troponin.
 - e. actin.
5. Which of the following muscle proteins is *not* intracellular?
 - a. actin
 - b. myosin
 - c. collagen
 - d. troponin
 - e. dystrophin
6. Smooth muscle cells have _____, whereas skeletal muscle fibers do not.
 - a. sarcoplasmic reticulum
 - b. tropomyosin
 - c. calmodulin
 - d. Z discs
 - e. myosin ATPase
7. ACh receptors are found mainly in
 - a. synaptic vesicles.
 - b. terminal cisterns.
 - c. thick filaments.
 - d. thin filaments.
 - e. junctional folds.
8. Unitary smooth muscle cells can stimulate each other because they have
 - a. a latch-bridge.
 - b. diffuse junctions.
 - c. gap junctions.
 - d. tight junctions.
 - e. cross-bridges.
9. A person with a high VO_2max
 - a. needs less oxygen than someone with a low VO_2max .
 - b. has stronger muscles than someone with a low VO_2max .
 - c. is less likely to show muscle tetanus than someone with a low VO_2max .
 - d. has fewer muscle mitochondria than someone with a low VO_2max .
 - e. experiences less muscle fatigue during exercise than someone with a low VO_2max .
10. Slow oxidative fibers have all of the following *except*
 - a. an abundance of myoglobin.
 - b. an abundance of glycogen.
 - c. high fatigue resistance.
 - d. a red color.
 - e. a high capacity to synthesize ATP aerobically.
11. The minimum stimulus intensity that will make a muscle contract is called _____.
12. Red muscles consist mainly of slow _____, or type I, muscle fibers.
13. Parts of the sarcoplasmic reticulum called _____ lie on each side of a T tubule.
14. Thick filaments consist mainly of the protein _____.
15. The neurotransmitter that stimulates skeletal muscle is _____.
16. Muscle contains an oxygen-binding pigment called _____.
17. The _____ of skeletal muscle play the same role as dense bodies in smooth muscle.
18. In autonomic nerve fibers that stimulate unitary smooth muscle, the neurotransmitter is contained in swellings called _____.
19. A state of continual partial muscle contraction is called _____.
20. _____ is an increase in muscle tension without a change in length.

▶ Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|-------------|-----------|-------------|

| | 6. myo- | 10. -trophy |

STUDY GUIDE

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. Each motor neuron supplies one muscle fiber.
2. Somatic motor neurons excite skeletal muscle but inhibit cardiac muscle.
3. Fast glycolytic muscle fibers are relatively resistant to fatigue.
4. Thin myofilaments are found only in the I bands of striated muscle.
5. Thin myofilaments shorten when a muscle contracts.
6. Smooth muscle lacks striations because it does not have thick and thin myofilaments.
7. A muscle must contract to the point of complete tetanus before it begins to move a load.
8. If no ATP were available to a muscle fiber, it could still be excited but it could not contract.
9. For the first 30 seconds of an intense exercise, muscle gets most of its energy from lactate.
10. Like cardiac muscle, all smooth muscle is autorhythmic.

► Testing Your Comprehension

1. Without ATP, relaxed muscle cannot contract and a contracted muscle cannot relax. Explain why.
2. Smooth muscle controls the curvature of the lens of the eye and the diameter of the pupil, but it would serve poorly for controlling eye movements as in tracking a flying bird or reading a page of print. Explain why.
3. Bicycles are designed so the rider leans forward at about a 45° angle rather than sitting upright. Aside from issues of wind resistance, explain the advantage of this in terms of musculoskeletal anatomy of the hip region and a physiological principle in this chapter.
4. As skeletal muscle contracts, one or more bands of the sarcomere become narrower and disappear, and one or more of them remain the same width. Which bands will change—A, H, or I—and why?
5. Polio is a muscle-paralyzing disease caused by infection with poliovirus. This virus, however, never infects muscular tissue. (a) Explain how it could paralyze the muscles without invading them. (b) Explain why it does not paralyze cardiac muscle and stop the heart.

NERVOUS TISSUE

Module 7: Nervous System

BRUSHING UP

- This chapter explains the electrophysiology of neurons and assumes you are familiar with concentration and electrochemical gradients (see section 1.6e).
- This topic also assumes familiarity with “Membrane Proteins” in section 3.2a—especially receptors, enzymes, ligand- and voltage-gated ion channels, leak channels, and the sodium–potassium pump.

The nervous system is one of great complexity and mystery, and will absorb our attention for the next five chapters. It is the foundation of all our conscious experience, personality, intellectual abilities, and behavior. It profoundly intrigues biologists, physicians, psychologists, and even philosophers. Its scientific study, called **neurobiology**, is regarded by many as the ultimate challenge facing the behavioral and life sciences. We will begin at the simplest organizational level—the nerve cells (*neurons*) and cells called *neuroglia* that support their function in various ways. We will then progress to the organ level to examine the spinal cord (chapter 13), brain (chapter 14), autonomic nervous system (chapter 15), and sense organs (chapter 16).

12.1 Overview of the Nervous System

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the overall function of the nervous system; and
- describe its major anatomical and functional subdivisions.

If the body is to maintain homeostasis and function effectively, its trillions of cells must work together in a coordinated fashion. If each cell behaved without regard to what others were doing, the result would be physiological chaos and death. We have two organ systems dedicated to maintaining internal coordination—the **endocrine system** (see chapter 17), which communicates by means of hormones secreted into the blood, and the **nervous system** (fig. 12.1), which employs **neurons (nerve cells)** to quickly send messages from cell to cell by electrical and chemical means.

The nervous system carries out its coordinating task in three basic steps: (1) It receives information about changes in the body and external environment (**stimuli**) and transmits messages to the *central nervous system (CNS)*. (2) The CNS processes this information and determines what response, if any, is appropriate to the circumstances. (3) The CNS issues commands primarily to muscle and gland cells to carry out such responses.

The nervous system has two major anatomical subdivisions (fig. 12.2):

- The **central nervous system (CNS)** consists of the brain and spinal cord, which are enclosed and protected by the cranium and vertebral column, respectively. The CNS performs most of the decision-making functions of the nervous system.

FIGURE 12.1 The Nervous System.

FIGURE 12.2 Divisions of the Nervous System.

- The **peripheral nervous system (PNS)** consists of all the rest; it is composed of nerves and ganglia. A **nerve** is a bundle of nerve fibers (axons) wrapped in fibrous connective tissue. Nerves emerge from the CNS through foramina of the skull and vertebral column and carry signals to and from other organs of the body. A **ganglion**¹ (plural, *ganglia*) is a knotlike swelling in a nerve where the cell bodies of PNS neurons are concentrated.

The peripheral nervous system is functionally divided into *sensory* and *motor* divisions, and each of these is further divided into *somatic* and *visceral* subdivisions.

- The **sensory (afferent²) division** carries signals from various **receptors** (sense organs and simple sensory nerve endings) to the CNS. This pathway informs the CNS of stimuli within and around the body.
 - The **somatic³ sensory division** carries signals from receptors in the skin, muscles, bones, and joints.
 - The **visceral sensory division** carries signals mainly from the viscera of the thoracic and abdominal cavities, such as the heart, lungs, stomach, and urinary bladder.
- The **motor (efferent⁴) division** carries signals from the CNS mainly to gland and muscle cells that carry out the body's responses. Cells and organs that respond to these signals are called **effectors**.
 - The **somatic motor division** carries signals to the skeletal muscles. This produces voluntary muscle contractions as well as automatic reflexes.
 - The **visceral motor division (autonomic⁵ nervous system, ANS)** carries signals to glands, cardiac muscle, and smooth muscle. We usually have no voluntary control over these effectors, and the ANS operates at an unconscious level. The responses of the ANS and its effectors are *visceral reflexes*. The ANS has three further divisions:
 - The **sympathetic division** tends to arouse the body for action—for example, by accelerating the heartbeat and increasing respiratory airflow—but it inhibits digestion and reduces urine production.
 - The **parasympathetic division** tends to have a calming effect—slowing the heartbeat, for example—but it stimulates digestion.
 - An extensive **enteric plexus**, which lies in the wall of the digestive tract, is composed of more neurons than the spinal cord. This system enables different regions of the long digestive tract to communicate and coordinate their motility and secretion, as discussed in later chapters (sections 15.2d and 25.1b).

The foregoing terms may give the impression that we have several nervous systems—central, peripheral, sensory, motor,

somatic, and visceral. These are just terms of convenience, however. There is only one nervous system, and these subsystems are interconnected parts of the whole.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. What is a receptor? How does a receptor differ from an effector? Give two examples of each.
2. Distinguish between the central and peripheral nervous systems, and between visceral and somatic divisions of the sensory and motor systems.
3. What is another name for the visceral motor nervous system? What are its three subdivisions? What are their functions?

12.2 Structure and Function of Neurons

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe three functional properties found in all neurons;
- b. define the three most basic functional categories of neurons;
- c. identify the parts of a neuron;
- d. describe four structural classes of neurons; and
- e. explain how neurons transport materials between the cell body and tips of the axon.

12.2a Universal Properties

Neurons have three fundamental physiological properties that enable them to communicate with other cells:

1. **Excitability.** All cells are excitable—that is, they respond to stimuli. Neurons exhibit this property to the highest degree.
2. **Conductivity.** Neurons respond to stimuli by producing electrical signals that are quickly conducted to other cells at distant locations.
3. **Secretion.** When the signal reaches the end of an axon, the neuron secretes a *neurotransmitter* that crosses the gap and stimulates the next cell.

▶▶▶ APPLY WHAT YOU KNOW

What basic physiological properties do a nerve cell and a muscle cell have in common? Name a physiological property of each that the other one lacks.

12.2b Functional Classes

There are three functional classes of neurons (**fig. 12.3**) corresponding to the three basic steps in nervous system function listed earlier:

- ① **Sensory (afferent) neurons** are specialized to detect stimuli such as light, heat, pressure, and chemicals, and transmit information about them to the CNS. Such neurons begin in almost

¹*gangli* = knot

²*af* = *ad* = toward; *fer* = to carry

³*somat* = body; *ic* = pertaining to

⁴*ef* = *ex* = out, away; *fer* = to carry

⁵*auto* = self; *nom* = law, governance

FIGURE 12.3 The Three Functional Classes of Neurons. All neurons can be classified as sensory, motor, or interneurons depending on their location and the direction of signal conduction.

every organ of the body and end in the CNS; the word *afferent* refers to signal conduction *toward* the CNS. Some receptors, such as those for pain and smell, are themselves neurons. In other cases, such as taste and hearing, the receptor is a separate cell that communicates directly with a sensory neuron.

- 2 **Interneurons** lie entirely within the CNS. They receive signals from many other neurons and carry out the integrative function of the nervous system—that is, they process, store, and retrieve information and “make decisions” that determine how the body responds to stimuli. About 90% of our neurons are interneurons. The word *interneuron* refers to the fact that they lie *between*, and interconnect, the incoming sensory pathways and the outgoing motor pathways of the CNS.
- 3 **Motor (efferent) neurons** send signals predominantly to muscle and gland cells, the effectors. They are called both *motor* neurons because most of them lead to muscle cells, and *efferent* neurons to signify signal conduction *away from* the CNS.

12.2c Structure of a Neuron

There are several varieties of neurons, but a good starting point for discussion is a motor neuron of the spinal cord (fig. 12.4). The control center of the neuron is called the **cell body** (sometimes *neurosoma*,⁶ *soma*, or *perikaryon*⁷). It has a centrally located

nucleus with a large nucleolus. The cytoplasm contains mitochondria, lysosomes, a Golgi complex, numerous inclusions, and an extensive rough endoplasmic reticulum and cytoskeleton. The cytoskeleton consists of a dense mesh of microtubules and **neurofibrils** (bundles of actin filaments), which compartmentalize the rough ER into dark-staining regions called **chromatophilic**⁸ **substance** (fig. 12.4e). This is unique to neurons and a helpful clue to identifying them in tissue sections with mixed cell types.

Mature neurons have no centrioles and can’t undergo any further mitosis after adolescence. Consequently, neurons that die are usually irreplaceable; surviving neurons cannot multiply to replace those lost. However, neurons are unusually long-lived cells, capable of functioning for over a hundred years. An interesting effect of the nonmitotic nature of neurons is that, although they experience independent changes in their DNA during early brain development, they can’t pass these mutations on to any daughter neurons. Consequently, there is substantial genetic variation from one neuron to another, especially in the brain—a state called *genomic mosaicism*. They vary greatly in nucleotide sequence and even in chromosome number. Neuroscientists believe that no two neurons in the brain are genetically identical, and researchers are now looking at this for clues to brain functions and neurological diseases.

The major inclusions in the cell body are glycogen granules, lipid droplets, melanin, and a golden brown pigment called *lipofuscin*⁹ (LIP-oh-FEW-sin), produced when lysosomes degrade worn-out organelles and other products. Lipofuscin accumulates with age and pushes the nucleus to one side of the cell. Lipofuscin granules are also called “wear-and-tear granules” because they’re most abundant in old neurons. They’re also associated with certain degenerative diseases such as macular degeneration of the eye and amyotrophic lateral sclerosis (ALS).

Most neurons have extensions called **neurites** reaching out to other cells. Most of these are **dendrites**¹⁰—named for their striking resemblance to the bare branches of a tree in winter. Dendrites are the primary sites for receiving signals from other neurons. Some neurons have only one dendrite and some have thousands. The more dendrites a neuron has, the more information it can receive and incorporate into its decision making. As tangled as the dendrites may seem, they provide exquisitely precise pathways for the reception and processing of neural information.

On one side of the cell body is a mound called the **axon hillock**, from which a solitary neurite called the **axon (nerve fiber)** originates. The axon is cylindrical and relatively unbranched for most of its length, although it may give rise to a few branches called *axon collaterals* near the cell body, and most axons branch extensively at their distal end. An axon is specialized for rapid conduction of nerve signals to points remote from the cell body. Its cytoplasm is called the **axoplasm** and its membrane the **axolemma**.¹¹ A neuron never has more than one axon, and some neurons have none.

Nerve cell bodies range from 5 to 135 μm in diameter, and axons from 1 to 20 μm in diameter and from a few millimeters to

⁶*soma* = body

(d) Neurofibrils of the cell body. (e) Chromatophilic substance, stained masses of rough ER separated by the bundles of neurofibrils shown in part (d). See section 12.3b for description of the myelin sheath.

more than a meter long. (In the great blue whale, one nerve cell can be more than 30 m, or 100 ft, long. Another contender for extraordinary length is nerve cells of the recurrent laryngeal nerve in the neck of a giraffe, measuring 4.6 m [15 ft] long.) The dimensions of a human neuron are more impressive when we scale them up to the size of familiar objects. If the cell body of a spinal motor neuron were the size of a tennis ball, its dendrites would form a dense bushy mass that could fill a 30-seat classroom from floor to ceiling. Its axon would be up to a mile long but a little narrower than a garden hose. This is quite a point to ponder. The neuron must assemble molecules and organelles in its “tennis ball” cell body and deliver them through its “mile-long garden hose” to the end of the axon. How it achieves this remarkable feat is explained shortly.

At the distal end, an axon usually has a **terminal arborization**¹²—an extensive complex of fine branches. Each branch ends in a bulbous **axon terminal (terminal bouton**¹³), which forms a junction called a *synapse* with the next cell in the signaling pathway.

Not all neurons fit the preceding description. Neurons are classified structurally according to the number of processes extending from the cell body (**fig. 12.5**):

- **Multipolar neurons** are those, like the preceding, that have one axon and multiple dendrites. This is the most common type and includes most neurons of the brain and spinal cord.
- **Bipolar neurons** have one axon and one dendrite. Examples include olfactory cells of the nose, certain neurons of the retina, and sensory neurons of the ear.
- **Unipolar neurons** have only a single process leading away from the cell body. They are represented by the neurons that carry signals to the spinal cord for such senses as touch and pain. They are also called *pseudounipolar* because they start out as bipolar neurons in the embryo, but their two processes fuse into one as the neuron matures. A short distance away from the cell body, the process branches like a T into a *peripheral process* and a *central process*. The peripheral process begins with a sensory ending often far away from the cell body—in the skin, for example. Its signals travel toward the cell body, but bypass it and continue along the central process for a short remaining distance to the spinal cord. The dendrites are considered to be only the short receptive endings. The rest of the process, both peripheral and central, is the axon, distinguished by the presence of myelin and the ability to generate action potentials.
- **Anaxonic neurons** have multiple dendrites but no axon. They communicate locally through their dendrites and don't produce action potentials. Some anaxonic neurons are found in the brain, retina, and adrenal medulla. In the retina, they help in visual processes such as the perception of contrast.

12.2d Axonal Transport

All of the proteins needed by a neuron must be made in the cell body, where the “protein factory” is located—nucleus, ribosomes, and rough endoplasmic reticulum. Yet many of these proteins are needed in the axon, for example to repair and maintain the axolemma, to serve as ion channels in the membrane, or to act in the axon terminal as enzymes and signaling molecules. Other substances are transported from the axon terminals back to the cell body for disposal or recycling. The two-way passage of proteins, organelles, and other materials along an axon is called **axonal transport**. Movement away from the cell body down the axon is called **anterograde**¹⁴ **transport** and movement up the axon toward the cell body is called **retrograde**¹⁵ **transport**.

Materials travel along axonal microtubules that act like mono-rail tracks to guide them to their destination. But what is the “engine” that drives them along the tracks? Anterograde transport employs a motor protein called *kinesin*¹⁶ and retrograde transport uses one called *dynein*¹⁷ (the same protein responsible for the motility of cilia and flagella). These proteins carry materials “on their backs” while they reach out, like the myosin heads of muscle described in chapter 11, to bind repeatedly to the microtubules and walk along them.

There are two types of axonal transport: fast and slow.

1. **Fast axonal transport** occurs at a rate of 200 to 400 mm/day and may be either anterograde or retrograde:
 - *Fast anterograde transport* moves mitochondria; synaptic vesicles; other organelles; components of the axolemma; calcium ions; enzymes such as acetylcholinesterase; and small molecules such as glucose, amino acids, and nucleotides toward the distal end of the axon.
 - *Fast retrograde transport* returns used synaptic vesicles and other materials to the cell body and informs it of conditions at the axon terminals. Some pathogens exploit this process to invade the nervous system. They enter the distal tips of an axon and travel to the cell body by retrograde transport. Examples include tetanus toxin and the herpes simplex, rabies, and polio viruses. In such infections, the delay between infection and the onset of symptoms corresponds to the time needed for the pathogens to reach the cell bodies.
2. **Slow axonal transport** is an anterograde process that works in a stop-and-go fashion. If we compare fast axonal transport to an express train traveling nonstop to its destination, slow axonal transport is like a local train that stops at every station. When moving, it goes just as fast as the express train, but the frequent stops result in an overall progress of only 0.2 to 0.5 mm/day. It moves enzymes and cytoskeletal components down the axon, renews worn-out

axoplasmic components in mature neurons, and supplies new axoplasm for developing or regenerating neurons. Damaged nerves regenerate at a speed governed by slow axonal transport.

▶▶▶ APPLY WHAT YOU KNOW

The axon of a neuron has a dense cytoskeleton. Considering the functions of the cytoskeleton discussed in section 3.4a, give two reasons why this is so important to neuron structure and function.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

4. Sketch a multipolar neuron and label its cell body, dendrites, axon, terminal arborization, axon terminals, and myelin sheath.
5. Explain the differences between a sensory neuron, motor neuron, and interneuron.
6. What is the functional difference between a dendrite and an axon?
7. How do proteins and other chemicals synthesized in the cell body get to the axon terminals? By what process can a virus that invades the distal end of an axon get to the cell body of that neuron?

12.3 Supportive Cells

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name the six types of cells that aid neurons, and state their respective functions;
- b. describe the myelin sheath that is found around certain axons, and explain its importance;
- c. describe the relationship of unmyelinated axons to their supportive cells; and
- d. explain how damaged axons regenerate.

There are approximately 86 billion neurons in the adult brain, and a roughly equal number of non-neuronal supportive cells called **neuroglia** (noo-ROG-lee-uh), or **glial cells** (GLEE-ul). Glial cells protect the neurons and help them function. The word *glia*, which means “glue,” implies one of their roles—to bind neurons together and provide a supportive framework for the nervous tissue. In the fetus, they form a scaffold that guides young migrating neurons to their destinations. Wherever a mature neuron is not in synaptic contact with another cell, it is covered with glial cells. This prevents neurons from contacting each other except at points specialized for signal transmission, thus giving precision to their conduction pathways.

¹⁴*antero* = forward; *grad* = to walk, to step

¹⁵*retro* = back; *grad* = to walk, to step

¹⁶*kines* = motion; *in* = protein

¹⁷*dyne* = force; *in* = protein

12.3a Types of Neuroglia

There are six kinds of neuroglia, each with a unique function (**table 12.1**). The first four, called *central glial cells*, occur only in the central nervous system (**fig. 12.6**):

1. **Oligodendrocytes**¹⁸ (OL-ih-go-DEN-dro-sites) somewhat resemble an octopus; they have a bulbous body with as many as 15 arms. Each arm reaches out to an axon and spirals around it like electrical tape wrapped repeatedly around a wire. This wrapping, called the *myelin sheath*, insulates the axon from the extracellular fluid and speeds up signal conduction in the axon.
2. **Ependymal**¹⁹ cells (ep-EN-dih-mul) resemble a cuboidal epithelium lining the internal cavities of the brain and spinal cord. Unlike true epithelial cells, however, they have no basement membrane and they exhibit rootlike processes that penetrate into the underlying tissue and connect with other cells. Ependymal cells produce *cerebrospinal fluid (CSF)*, a liquid that bathes the CNS and fills its internal cavities. They have patches of cilia on their apical surfaces that help to circulate the CSF. Ependymal cells and CSF are considered in more detail in chapter 14.
3. **Microglia** are small macrophages that develop from white blood cells called monocytes. They wander through the CNS, putting out fingerlike extensions to constantly probe the tissue for cellular debris or other problems. They are

¹⁸*oligo* = few; *dendro* = branches; *cyte* = cell

¹⁹*ependyma* = upper garment

TABLE 12.1 Types of Glial Cells	
Types	Functions
Central Glial Cells	
Oligodendrocytes	Form myelin in brain and spinal cord
Ependymal cells	Line cavities of brain and spinal cord; secrete and circulate cerebrospinal fluid
Microglia	Phagocytize and destroy microorganisms, foreign matter, and dead nervous tissue
Astrocytes	Cover brain surface and nonsynaptic regions of neurons; form supportive framework in CNS; induce formation of blood–brain barrier; nourish neurons; produce growth factors that stimulate neurons; promote the formation of synapses and neural circuitry; communicate electrically with neurons and may influence synaptic signaling; remove K ⁺ and some neurotransmitters from ECF of brain and spinal cord; help to regulate composition of ECF; form scar tissue to replace damaged nervous tissue
Peripheral Glial Cells	
Schwann cells	Form neurolemma around all PNS axons and myelin around most of them; aid in regeneration of damaged nerves
Satellite cells	Surround cell bodies of neurons in the ganglia; provide electrical insulation and regulate chemical environment of neurons

FIGURE 12.6 Neuroglia of the Central Nervous System.

thought to perform a complete checkup on the brain tissue several times a day, phagocytizing dead tissue, microorganisms, and other foreign matter. They become concentrated in areas damaged by infection, trauma, or stroke. Pathologists look for clusters of microglia in brain tissue as a clue to sites of injury or degeneration. Microglia also aid in synaptic remodeling, changing the connections between neurons.

4. **Astrocytes**²⁰ are the most abundant glial cells in the CNS and constitute over 90% of the tissue in some areas of the brain. They cover the entire brain surface and most non-synaptic regions of the neurons in the gray matter. They are named for their many-branched, somewhat starlike shape. They have the most diverse functions of any glia:

- They form a supportive framework for the nervous tissue.
- They have extensions called *perivascular feet*, which contact the blood capillaries and stimulate them to form a tight, protective seal called the *blood–brain barrier* (see chapter 14).
- They monitor neuron activity, stimulate dilation and constriction of blood vessels, and thus regulate blood flow in the brain tissue to meet changing needs for oxygen and nutrients.
- They convert blood glucose to lactate and supply this to the neurons for nourishment.
- They secrete *nerve growth factors* that regulate nerve development (see Deeper Insight 12.3).
- They promote synapse formation and fine-tune neural circuitry.
- They communicate electrically with neurons and influence synaptic signaling between them.
- They regulate the composition of the tissue fluid. When neurons transmit signals, they release neurotransmitters and potassium ions. Astrocytes absorb these and prevent them from reaching excessive levels in the tissue fluid.
- When neurons are damaged, astrocytes form hardened scar tissue and eventually fill space formerly occupied by the neurons. This process is called *astrocytosis* or *sclerosis*.

The remaining types, found only in the peripheral nervous system, are called *peripheral glial cells*:

1. **Schwann**²¹ cells (pronounced “shwon”), or **neurilemmocytes**, envelop axons of the PNS. In most cases, a Schwann cell winds repeatedly around an axon and produces a myelin sheath similar to the one produced by oligodendrocytes in the CNS. There are some important differences in myelin production between the CNS and PNS, which we consider shortly. Schwann cells also assist in the regeneration of damaged axons (see section 12.3e).
2. **Satellite cells** surround the nerve cell bodies in ganglia of the PNS. They provide insulation around the cell body and regulate the chemical environment of the neurons.

²⁰*astro* = star; *cyte* = cell

DEEPER INSIGHT 12.1

CLINICAL APPLICATION

Glial Cells and Brain Tumors

A tumor consists of a mass of rapidly dividing cells. Mature neurons, however, have little or no capacity for mitosis and seldom form tumors. Some brain tumors arise from the meninges (protective membranes of the CNS) or arise by metastasis from tumors elsewhere, such as malignant melanoma and colon cancer. Most adult brain tumors, however, are composed of glial cells, which are mitotically active throughout life. Such tumors are called *gliomas*²² (fig. 12.7). Gliomas usually grow rapidly and are highly malignant. Because of the blood–brain barrier, brain tumors resist chemotherapy and must be treated with radiation or surgery.

FIGURE 12.7 Brain Tumor. Frontal section of the brain showing a large glioma in the left cerebral hemisphere.

CNRI/Science Source

12.3b Myelin

The **myelin sheath** (MY-eh-lin) consists of spiral layers of insulation around an axon, formed by Schwann cells in the PNS and oligodendrocytes in the CNS. Myelin consists of the plasma membranes of these glial cells. Like them, it is made of protein and lipid, but has some unique lipids.

Production of the myelin sheath is called **myelination**. It begins in the fourteenth week of fetal development, yet hardly any

²²*glia* = glial cells; *oma* = tumor

myelin exists in the brain at the time of birth. Myelination proceeds rapidly in infancy and isn't completed until late adolescence. Since myelin has such a high lipid content, dietary fat is important to early nervous system development. It is best not to give children under 2 years old the sort of low-fat diets (skimmed milk, etc.) that may be beneficial to an adult.

In the PNS, a Schwann cell spirals repeatedly around a single axon, laying down up to 100 compact layers of its own membrane with almost no cytoplasm between the membranes (**fig. 12.8a**). These layers constitute the myelin sheath. The Schwann cell spirals outward as it wraps the axon, finally ending with a thick outermost coil called the **neurolemma**²³ (noor-o-LEM-ah). Here, the bulging body of the Schwann cell contains its nucleus and most of its cytoplasm. External to the neurolemma is a basal lamina and then a thin sleeve of fibrous connective tissue called the *endoneurium*. To visualize this myelination process, imagine that you wrap an almost-empty tube of toothpaste tightly around a pencil. The pencil represents the axon, and the spiral layers of toothpaste tube represent the myelin. The toothpaste, like the cytoplasm of the cell, would be forced to one end of the tube and form a bulge on the external surface of the wrapping, like the body of the Schwann cell.

In the CNS, each oligodendrocyte reaches out to myelinate several axons in its immediate vicinity (**fig. 12.8b**). Since it is anchored to multiple axons, it can't migrate around any one of them like a Schwann cell does. It pushes newer layers of myelin under the older ones, so myelination spirals inward toward the axon. Axons of the CNS have no neurolemma or endoneurium. The contrasting modes of myelination are called *centrifugal myelination* ("away from the center") in the PNS and *centripetal myelination* ("toward the center") in the CNS.

In both the PNS and CNS, axons are much longer than the reach of a single glial cell, so it requires many Schwann cells or oligodendrocytes to cover one axon. Consequently, the myelin sheath is segmented. Each gap between segments is called a **myelin sheath gap** or **node of Ranvier**²⁴ (RON-vee-AY) (*node* for short); the myelin-covered segments from each node to the next are called **internodal segments** (see **fig. 12.4a**). These segments are about 0.2 to 1.0 mm long. The short section of axon between the axon hillock and the first glial cell is called the **initial segment**. Since the axon hillock and initial segment play an important role in initiating a nerve signal, they are collectively called the **trigger zone**.

12.3c Unmyelinated Axons

Many axons in the CNS and PNS are unmyelinated. In the PNS, however, even the unmyelinated axons are enveloped in Schwann cells (**fig. 12.9**). The Schwann cell's plasma membrane doesn't spiral repeatedly around the axon as it does in a myelin sheath, but folds once around each axon and may overlap itself along the edges. This wrapping is the neurolemma. Several unmyelinated

axons travel through individual channels in a shared Schwann cell. A basal lamina surrounds the entire Schwann cell along with its axons.

12.3d Conduction Speed of Axons

The speed at which a nerve signal travels along an axon depends on two factors: the diameter of the axon and the presence or absence of myelin. Signal conduction occurs along the surface of an axon, not deep within its axoplasm. Large axons have more surface area and conduct signals more rapidly than small ones. Myelin further speeds signal conduction by a mechanism to be explained in section 12.4f. Nerve signals travel about 0.5 to 2.0 m/s in small unmyelinated axons (2–4 μm in diameter); 3 to 15 m/s in myelinated axons of the same size; and as fast as 120 m/s (270 mph!) in large myelinated axons (up to 20 μm in diameter). One may wonder why all of our axons aren't large, myelinated, and fast; but if this were so, our nervous system would be impossibly bulky or limited to far fewer neurons. Large axons require large cell bodies and a large expenditure of energy to maintain them. The evolution of myelin allowed for the subsequent evolution of more complex and responsive nervous systems with smaller, more energy-efficient neurons. Slow unmyelinated axons are quite sufficient for processes in which quick

CLINICAL APPLICATION

Diseases of the Myelin Sheath

Multiple sclerosis and Tay–Sachs disease are degenerative disorders of the myelin sheath. In **multiple sclerosis**²⁵ (**MS**), the oligodendrocytes and myelin sheaths of the CNS deteriorate and are replaced by hardened scar tissue, especially between the ages of 20 and 40. Nerve conduction is disrupted, with effects that depend on what part of the CNS is involved—double vision, blindness, speech defects, neurosis, tremors, or numbness, for example. Patients experience variable cycles of milder and worse symptoms until they eventually become bedridden. The cause of MS remains uncertain; most hypotheses suggest that it is an autoimmune disorder triggered by a virus in genetically susceptible individuals. There is no cure. There is conflicting evidence of how much it shortens a person's life expectancy, if at all. A few die within 1 year of diagnosis, but many people live with MS for 25 or 30 years.

Tay–Sachs²⁶ **disease** is a hereditary disorder seen mainly in infants of Eastern European Jewish ancestry. It results from the abnormal accumulation of a glycolipid called GM₂ (ganglioside) in the myelin sheath. GM₂ is normally decomposed by a lysosomal enzyme, but this enzyme is lacking from people who are homozygous recessive for the Tay–Sachs allele. As GM₂ accumulates, it disrupts the conduction of nerve signals and the victim typically suffers blindness, loss of coordination, and dementia. Signs begin to appear before the child is a year old, and most victims die by the age of 3 or 4 years. Asymptomatic adult carriers can be identified by a blood test and advised by genetic counselors on the risk of their children having the disease.

²³neuro = nerve; lemma = husk, peel, sheath

? What is the functional disadvantage of an unmyelinated axon? What is its anatomical advantage?

responses aren't particularly important, such as secreting stomach acid or dilating the pupil. Fast myelinated axons are employed where speed is more important, as in motor commands to the skeletal muscles and sensory signals for vision and balance.

12.3e Nerve Regeneration

Nerves of the PNS are vulnerable to cuts, crushing injuries, and other trauma. They can often regenerate, however, if the nerve cell bodies are intact and at least some neurolemma remains. **Figure 12.10** shows the process of regeneration, taking as its example a somatic motor neuron:

- 1 In the normal neuron, note the size of the cell body and the size of the muscle fibers for comparison to later stages.
- 2 When an axon is cut, the portion distal to the injury can't survive because it is incapable of protein synthesis. Protein-synthesizing organelles are mostly in the cell body. As the distal part of the axon degenerates, so do its Schwann cells, which depend on it for their maintenance. Macrophages clean up tissue debris at the point of injury and beyond.
- 3 The cell body exhibits a number of abnormalities of its own, probably because it is cut off from the supply of nerve growth factors from the neuron's target cells

FIGURE 12.10 Regeneration of a Damaged Axon. See numbered steps in text for explanation. Axons of the PNS can regenerate if the cell body and some neurolemma are intact.

(see Deeper Insight 12.3). The cell body swells, the endoplasmic reticulum breaks up (so the chromatophilic substance disperses), and the nucleus moves off center. Not all damaged neurons survive; some die at this stage. But often, the axon stump sprouts multiple growth processes while the severed distal end shows continued degeneration of its axon and Schwann cells. Muscle fibers deprived of their nerve supply exhibit a shrinkage called *denervation atrophy*.

- 4 Near the injury, the Schwann cell neurolemma, endoneurium, and basal lamina form a **regeneration tube**. The Schwann cells produce cell-adhesion molecules and nerve growth factors that enable a neuron to regrow to its original destination. When one growth process finds its way into the tube, it grows rapidly (3–5 mm/day), and the other growth processes are retracted.
- 5 The regeneration tube guides the growing sprout back to the original target cells, reestablishing synaptic contact.
- 6 When contact is established, the nerve cell body shrinks and returns to its original appearance, and the reinnervated muscle fibers regrow.

Regeneration isn't perfect. Some axons connect to the wrong muscle fibers or never find a muscle fiber at all, and some damaged neurons simply die. Nerve injury is therefore often followed by some degree of functional deficit. Even when regeneration is achieved, the slow rate of axon regrowth means that some nerve function may take as long as 2 years to recover.

Schwann cells and endoneurium are required for axonal regeneration. Both of these are lacking from the CNS, so damaged CNS axons can't regenerate at all. However, since the CNS is encased in bone, it suffers less trauma than the peripheral nerves.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

8. How is a glial cell different from a neuron? List the six types of glial cells and discuss their functions.
9. How is myelin produced? How does myelin production in the CNS differ from that in the PNS?
10. How can a severed peripheral axon find its way back to the cells it originally innervated?

12.4 Electrophysiology of Neurons

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain why a cell has an electrical charge difference (voltage) across its membrane;
- b. explain how stimulation of a neuron causes a local electrical response in its membrane;
- c. explain how local responses generate a nerve signal; and
- d. explain how the nerve signal is conducted down an axon.

The nervous system has intrigued scientists and philosophers since ancient times. Galen, the preeminent physician of ancient Rome, thought that the brain pumped a vapor called *psychic pneuma* through hollow nerves and squirted it into the muscles to make them contract. The French philosopher René Descartes still argued for this theory in the seventeenth century. It finally fell out of favor in the eighteenth century, when Luigi Galvani discovered the role of electricity in muscle contraction (see Deeper Insight 11.3). Further progress had to await improvements in microscope technology and histological staining methods. Italian histologist Camillo Golgi (1843–1926) developed an important method for staining neurons with silver. Spanish histologist Santiago Ramón y Cajal (1852–1934) employed the Golgi stain to trace the course of nerve processes over long distances through serial tissue sections. Working with tremendous skill and patience under primitive conditions—setting up a lab at his kitchen table between meals—he demonstrated that the nervous pathway wasn't a continuous “wire” or tube, but a series of cells separated by the gaps we now call synapses. Golgi and Cajal, even though they feuded over this and intensely disliked each other, shared the 1906 Nobel Prize for Physiology or Medicine for these important discoveries.

Cajal's theory suggested another direction for research: How do neurons communicate? Two key issues in neurophysiology are (1) How does a neuron generate an electrical signal? and (2) How does it transmit a meaningful message to the next cell? These are the questions to which this section and the next are addressed.

12.4a Electrical Potentials and Currents

Neural communication, like muscle excitation, is based on electrophysiology—cellular mechanisms for producing electrical potentials and currents. An **electrical potential** is a difference in the concentration of charged particles between one point and another. It is a form of potential energy that, under the right circumstances, can produce a current. An electrical **current** is a flow of charged particles from one point to another. A new flashlight battery, for example, typically has a potential, or charge, of 1.5 volts (V). If a lightbulb and the two poles of the battery are connected by a wire, electrons flow through the wire from one pole to the other, creating a current that lights the bulb. As long as the battery has a potential (voltage), we say it is **polarized**.

Living cells are also polarized. The charge difference across the plasma membrane is called the **resting membrane potential (RMP)**. It is much less than the potential of a flashlight battery—typically about –70 millivolts (mV) in an unstimulated, “resting” neuron. The negative value means there are more negatively charged particles on the inside of the membrane than on the outside.

We don't have free electrons in the body as we do in an electrical circuit. Electrical currents in the body are created, instead, by the flow of ions such as Na^+ and K^+ through gated channels in the plasma membrane. Gated channels can be opened and closed by various stimuli, as we have seen earlier (see “Membrane Proteins” in section 3.2a and “Electrically Excitable Cells,” section 11.3c). This enables cells to turn electrical currents on and off.

DEEPER INSIGHT 12.3

MEDICAL HISTORY

Nerve Growth Factor—From Home Laboratory to Nobel Prize

It is remarkable what odds can be overcome by self-confident persistence. Neurobiologist Rita Levi-Montalcini (**fig. 12.11**) affords a striking example. Although born into a cultured and accomplished Italian Jewish family, she and her twin sister Paola were discouraged from considering a college education or career by their tradition-minded father. Determined to attend university anyway, they hired their own tutor to prepare them. Rita graduated summa cum laude in medicine and surgery in 1930 and embarked on advanced study in neurology. Paola became a renowned artist.

But then arose the sinister specter of anti-Semitism, as fascist dictator Mussolini barred Jews from professional careers. Rita despaired of pursuing medicine or research until a college friend reminded her of how much Cajal had achieved under very primitive conditions. That inspired her to set up a little laboratory in her bedroom, where she studied nervous system development in chick embryos. She had read of work by Viktor Hamburger in St. Louis, who believed that limb tissues secrete a chemical that attracts nerves to grow into them. Levi-Montalcini, however, believed that nerves grow into the limbs without such attractants, but die if they fail to receive a substance needed to sustain them.

Fleeing first from Allied bombing and then Hitler's invasion of Italy, Levi-Montalcini had to abandon her work as the family went underground until the end of the war. At war's end, Hamburger invited her to join him in America, where they found her hypothesis to be correct. She and Stanley Cohen isolated the nerve-sustaining substance and named it *nerve growth factor (NGF)*, for which they shared a 1986 Nobel Prize. NGF is a protein secreted by muscle and glial cells. It prevents apoptosis in growing neurons and thus enables them to establish connections with their target cells. It was the first of many cell growth factors discovered, and launched what is today a vibrant field of research in the use of growth factors to stimulate tissue development and repair.

FIGURE 12.11 Rita Levi-Montalcini (1909–2012).

Olycom/SIPA/Newscom

Rita and Paola created the Levi-Montalcini Foundation to support the career development of young people and especially the scientific education of women in Africa. Rita also served as an honored member of the Italian Senate from 2001 until 2012, when she died at the age of 103.

12.4b The Resting Membrane Potential

The reason a cell has a resting membrane potential is that electrolytes are unequally distributed between the extracellular fluid (ECF) on the outside of the plasma membrane and the intracellular fluid (ICF) on the inside. The RMP results from the combined effect of three factors: (1) the diffusion of ions down their concentration gradients through the membrane; (2) selective permeability of the membrane, allowing some ions to pass more easily than others; and (3) the electrical attraction of cations and anions to each other.

Potassium ions (K^+) have the greatest influence on the RMP because the plasma membrane is more permeable to K^+ than to any other ion. Imagine a hypothetical cell in which all the K^+ starts out in the ICF, with none in the ECF. Also in the ICF are a number of cytoplasmic anions that cannot escape from the cell because of their size or charge—phosphates, sulfates, small organic acids, proteins, ATP, and RNA. Potassium ions diffuse freely through leak channels in the plasma membrane, down their concentration gradient and out of the cell, leaving these cytoplasmic anions behind (**fig. 12.12**). As a result, the ICF grows more and more negatively

FIGURE 12.12 Ionic Basis of the Resting Membrane Potential. Note that sodium ions are much more concentrated in the extracellular fluid (ECF) than in the intracellular fluid (ICF), whereas potassium ions are more concentrated in the ICF. Large anions unable to penetrate the plasma membrane give the cytoplasm a negative charge relative to the ECF.

charged. But as the ICF becomes more negative, it exerts a stronger attraction for the positive potassium ions and attracts some of them back into the cell. Eventually an *equilibrium* is reached in which K^+ is moving out of the cell (down its concentration gradient) and into the cell (by electrical attraction) at equal rates. There is no further *net* diffusion of K^+ . At the point of equilibrium, K^+ is about 40 times as concentrated in the ICF as in the ECF.

If K^+ were the only ion affecting the RMP, it would give the membrane a potential of about -90 mV. However, sodium ions (Na^+) also enter the picture. Sodium is about 12 times as concentrated in the ECF as in the ICF. The resting plasma membrane is much less permeable to Na^+ than to K^+ , but Na^+ does diffuse down its concentration gradient into the cell, attracted by the negative charge in the ICF. This sodium leak is only a trickle, but it is enough to cancel some of the negative charge and reduce the voltage across the membrane.

Sodium leaks into the cell and potassium leaks out, but the sodium–potassium (Na^+-K^+) pump continually compensates for this leakage. It pumps 3 Na^+ out of the cell for every 2 K^+ it brings in, consuming 1 ATP for each exchange cycle (see fig. 3.19). By removing more cations from the cell than it brings in, it contributes about -3 mV to the RMP. The resting membrane potential of -70 mV is the net effect of all these ion movements— K^+ diffusion out of the cell, Na^+ diffusion inward, and the Na^+-K^+ pump continually offsetting this ion leakage.

The Na^+-K^+ pump accounts for about 70% of the energy (ATP) requirement of the nervous system. Every signal generated by a neuron slightly upsets the distribution of Na^+ and K^+ , so the pump must work continually to restore equilibrium. This is why nervous tissue has one of the highest rates of ATP consumption of any tissue in the body, and why it demands so much glucose and oxygen. Although a neuron is said to be resting when it's not producing signals, it is highly active maintaining its RMP and “waiting,” as it were, for something to happen.

The uneven distribution of Na^+ and K^+ on the two sides of the plasma membrane pertains only to a very thin film of ions immediately adjacent to the membrane surfaces. The electrical events we are about to examine don't involve ions very far away from the membrane in either the ECF or the ICF.

12.4c Local Potentials

Stimulation of a neuron causes local disturbances in membrane potential. Typically (but with exceptions), the response begins at a dendrite, spreads through the cell body, travels down the axon, and ends at the axon terminal. We consider the process in that order.

Various neurons can be stimulated by chemicals, light, heat, or mechanical forces. We'll take as our example a neuron being chemically stimulated (fig. 12.13). The chemical (ligand)—perhaps a pain signal from a damaged tissue or odor molecule in a breath of air—binds to receptors on the neuron. This opens ligand-gated sodium channels that allow Na^+ to flow into the cell. The Na^+ inflow cancels some of the internal negative charge, so the voltage across the membrane at that point drifts toward zero, reducing the membrane polarity. Any such case in which the voltage shifts to a less negative value is called **depolarization**.

FIGURE 12.13 Excitation of a Neuron by a Chemical Stimulus.

The incoming Na^+ diffuses for short distances along the inside of the plasma membrane, creating a wave of depolarization that spreads out from the point of stimulation, like ripples spreading across a pond when you drop a stone into it. This short-range change in voltage is called a **local potential**. There are four characteristics that distinguish local potentials from the action potentials we will study in the next section (table 12.2). You will appreciate these distinctions more fully after you have studied action potentials.

1. Local potentials are **graded**, meaning they vary in magnitude (voltage) according to the strength of the stimulus. An intense or prolonged stimulus opens more gated ion channels than a weaker stimulus, and they stay open longer. Thus, more Na^+ enters the cell and the voltage changes more than it does with a weaker stimulus.
2. Local potentials are **decremental**, meaning they get weaker as they spread from the point of origin. They decline in strength partly because the Na^+ leaks back out of the cell through channels along its path, and partly because as Na^+ spreads out under the plasma membrane and depolarizes it, K^+ flows out and reverses the effect of the Na^+ inflow. Therefore, the voltage shift caused by Na^+ diminishes rapidly with distance. This prevents local potentials from having long-distance effects.
3. Local potentials are **reversible**, meaning that if stimulation ceases, cation diffusion out of the cell quickly returns the membrane voltage to its resting potential.
4. Local potentials can be either **excitatory** or **inhibitory**. So far, we have considered only excitatory local potentials, which depolarize a cell and make a neuron more likely to

produce an action potential. Acetylcholine usually has this effect. Other neurotransmitters, such as glycine, cause an opposite effect—they **hyperpolarize** a cell, or make the membrane more negative. This inhibits a neuron, making it less sensitive and less likely to produce an action potential. A balance between excitatory and inhibitory potentials is very important to information processing in the nervous system (see section 12.6b).

12.4d Action Potentials

An **action potential** is a more dramatic change produced by voltage-gated ion channels in the plasma membrane. Action potentials occur only where there is a high enough density of voltage-gated channels. Most of the cell body has only 50 to 75 channels per square micrometer (μm^2) of membrane, not dense enough to generate action potentials. The trigger zone, however, has 350 to 500 channels/ μm^2 . If an excitatory local potential spreads all the way to the trigger zone and is still strong enough when it arrives, it can open these channels and generate an action potential.

The action potential is a rapid up-and-down shift in voltage.

Figure 12.14a shows an action potential numbered to correspond to the following description.

- ① When the local current arrives at the axon hillock, it depolarizes the membrane at that point. This appears as a steadily rising local potential.
- ② For anything more to happen, this local potential must rise to a critical voltage called the **threshold** (typically about -55 mV), the minimum needed to open voltage-gated channels.
- ③ The neuron now “fires,” or produces an action potential. At threshold, voltage-gated Na^+ channels open quickly, while

gated K^+ channels open more slowly. The initial effect on membrane potential is therefore due to Na^+ . Initially, only a few Na^+ channels open, but as Na^+ enters the cell, it further depolarizes the membrane. This stimulates still more voltage-gated Na^+ channels to open and admit even more Na^+ , a positive feedback loop that causes the membrane voltage to rise even more rapidly.

- ④ As the rising potential passes 0 mV, Na^+ channels are *inactivated* and begin closing. By the time they all close and Na^+ inflow ceases, the voltage peaks at approximately $+35$ mV. (The peak is as low as 0 mV in some neurons and as high as 50 mV in others.) The membrane is now positive on the inside and negative on the outside—its polarity is reversed compared to the RMP.
- ⑤ By the time the voltage peaks, the slow K^+ channels are fully open. Potassium ions, repelled by the positive ICF, now exit the cell. Their outflow **repolarizes** the membrane—that is, it shifts the voltage back into the negative numbers. The action potential consists of the up-and-down voltage shifts that occur from the time the threshold is reached to the time the voltage returns to the RMP.
- ⑥ Potassium channels stay open longer than Na^+ channels, so slightly more K^+ leaves the cell than the amount of Na^+ that entered. Therefore, the membrane voltage drops to 1 or 2 mV more negative than the original RMP, producing a negative overshoot called *hyperpolarization*.
- ⑦ As you can see, Na^+ and K^+ switch places across the membrane during an action potential. During hyperpolarization, the membrane voltage gradually returns to the RMP because of Na^+ diffusion into the cell.

FIGURE 12.14 An Action Potential. (a) Diagrammed with a distorted timescale to make details of the action potential visible. Numbers correspond to stages discussed in the text. (b) On a more accurate timescale, the local potential is so brief it is imperceptible, the action potential appears as a spike, and the hyperpolarization is very prolonged.

TABLE 12.2 Comparison of Local Potentials and Action Potentials	
Local Potential	Action Potential
Produced by gated channels on the dendrites and nerve cell body	Produced by voltage-gated channels on the trigger zone and axon
May be a positive (depolarizing) or negative (hyperpolarizing) voltage change	Always begins with depolarization
Graded; proportional to stimulus strength	All or none; either does not occur at all or exhibits the same peak voltage regardless of stimulus strength
Reversible; returns to RMP if stimulation ceases before threshold is reached	Irreversible; goes to completion once it begins
Local; has effects for only a short distance from point of origin	Self-propagating; has effects a great distance from point of origin
Decremental; signal grows weaker with distance	Nondecremental; signal maintains same strength regardless of distance

Figure 12.14a is deliberately distorted. To demonstrate the different phases of the local potential and action potential, the magnitudes of the local potential and hyperpolarization are exaggerated, the local potential is stretched out to make it seem longer, and the duration of hyperpolarization is shrunken so the graph will fit the page. When these events are plotted on a more realistic timescale, they look more like **figure 12.14b**. The local potential is so brief it is unnoticeable, and hyperpolarization is very long but only slightly more negative than the RMP. An action potential is often called a *spike*; it is easy to see why from this figure.

Figure 12.15 correlates these voltage changes with events in the plasma membrane. At the risk of being misleading, it is drawn as if most of the Na^+ and K^+ had traded places. In reality, only about one in a million ions crosses the membrane to produce an action potential, and an action potential involves only the thin layer of ions close to the membrane. If the illustration tried to represent these points accurately, the difference would be so slight you couldn't see it. Even after thousands of action potentials, the cytosol still has a higher concentration of K^+ and a lower concentration of Na^+ than the ECF does.

Earlier we saw that local potentials are graded, decremental, and reversible. We can now contrast this with action potentials (table 12.2).

- Action potentials follow an **all-or-none law**. If a stimulus depolarizes the neuron to threshold, the neuron fires at its maximum voltage (such as +35 mV); if threshold is not reached, the neuron doesn't fire at all. Above threshold, stronger stimuli don't produce stronger action potentials. Thus, action potentials are not graded (proportional to stimulus strength) like local potentials are.
- Action potentials are **nondecremental**. They don't get weaker with distance. The last action potential at the end of an axon is just as strong as the first one in the trigger zone, no matter how far away—even in a pain fiber that extends from your toes to your brainstem.
- Action potentials are **irreversible**. If a neuron reaches threshold, the action potential goes to completion; it can't be stopped once it begins.

In some respects, we can compare the firing of a neuron to the firing of a gun. As the trigger is squeezed, a gun either fires with maximum force or doesn't fire at all (analogous to the all-or-none law). You can't fire a fast bullet by squeezing the trigger hard or a slow bullet by squeezing it gently—once the trigger is pulled to its “threshold,” the bullet always leaves the muzzle at the same velocity. And, like an action potential, the firing of a gun is irreversible once the threshold is reached; neither a bullet nor an action potential can be called back. Table 12.2 further contrasts a local potential with an action potential, including some characteristics of action potentials explained in the following sections.

12.4e The Refractory Period

During an action potential and for a few milliseconds after, it is difficult or impossible to stimulate that region of a neuron to fire again. This period of resistance to restimulation is called the **refractory period**. It is divided into two phases: an *absolute refractory period* in which no stimulus of any strength will trigger a new action potential, followed by a *relative refractory period* in which it is possible to trigger a new action potential, but only with an unusually strong stimulus (**fig. 12.16**).

The absolute refractory period lasts from the start of the action potential until the membrane returns to the resting potential—that is, for as long as the Na^+ channels are open and subsequently inactivated. The relative refractory period lasts until hyperpolarization ends. During this period, K^+ channels are still open. A new stimulus tends to admit Na^+ and depolarize the membrane, but K^+ diffuses out through the open channels as Na^+ comes in, and thus opposes the effect of the stimulus. It requires an especially strong stimulus to override the K^+ outflow and depolarize the cell enough to set off a new action potential. By the end of hyperpolarization, K^+ channels are closed and the cell is as responsive as ever.

The refractory period refers only to a small patch of membrane where an action potential has already begun, not to the entire neuron. Other parts of the neuron can still be stimulated while a small area of it is refractory, and even this area quickly recovers once the nerve signal has passed.

FIGURE 12.15 Actions of the Sodium and Potassium Channels During an Action Potential. The red part of each graph shows the point in the action potential where the events of steps 1 through 4 occur. **APR**

12.4f Signal Conduction in Axons

If a neuron is to communicate with another cell, a signal has to travel to the end of the axon. We now examine how this is achieved.

Unmyelinated Axons and Continuous Conduction

Unmyelinated axons present a relatively simple case of signal conduction, easy to understand based on what we have already covered (**fig. 12.17**). An unmyelinated axon has voltage-gated channels along its entire length. When an action potential occurs at the trigger zone, Na^+ enters the neuron and diffuses for a short distance just beneath the plasma membrane. The resulting depolarization excites voltage-gated

channels immediately distal to the action potential. Sodium and potassium channels open and close just as they did at the trigger zone, and a new action potential is produced. By repetition, this excites the membrane immediately distal to that. This chain reaction continues until the traveling signal reaches the end of the axon. Because this produces an uninterrupted wave of electrical excitation all along the axon, this mechanism is called **continuous conduction**.

Note that an action potential itself doesn't travel along an axon; rather, it stimulates the production of a new action potential in the membrane just ahead of it. Thus, we can distinguish an action potential from a nerve signal. The **nerve signal** is a traveling wave of excitation produced by self-propagating action potentials. It's like a

FIGURE 12.16 The Absolute and Relative Refractory Periods in Relation to the Action Potential. The neuron's membrane is in an absolute refractory period during the action potential (magenta zone, •); in its relative refractory period immediately thereafter (yellow, ••); and fully charged and excitable in the green zones (•••) of the curve.

line of falling dominoes. No one domino travels to the end of the line, but each domino pushes over the next one and there is a transmission of energy from the first domino to the last. Similarly, no one action potential travels to the end of an axon; a nerve signal is a chain reaction of action potentials, each triggering the next one ahead of it.

If one action potential stimulates the production of a new one next to it, you might think that the signal could also start traveling backward and return to the cell body. This doesn't occur, however, because the membrane immediately behind the nerve signal is still in its refractory period and can't be restimulated. Only the membrane ahead is sensitive to stimulation. The refractory period thus ensures that nerve signals are conducted in the proper direction, from the cell body to the axon terminals.

A traveling nerve signal is an electrical current, but it isn't the same as a current traveling through a wire. A current in a wire travels millions of meters per second and is decremental—it gets weaker with distance. A nerve signal is much slower (not more than 2 m/s in unmyelinated axons), but as already noted, it is nondecremental. To clarify this concept, we can compare the nerve signal to a burning fuse on a firecracker. When a fuse is lit, the heat ignites powder immediately in front of this point, and this repeats itself in a self-propagating fashion until the end of the fuse is reached. At the end, the fuse burns just as hotly as it did at the beginning. In a fuse, the combustible powder is the source of potential energy that keeps the process going in a nondecremental fashion. In an axon, the potential energy comes from the ion gradient across the plasma membrane. Thus, the signal doesn't grow weaker with distance; it is self-propagating, like the burning of a

FIGURE 12.17 Continuous Conduction of a Nerve Signal in an Unmyelinated Axon. Note that the membrane polarity is reversed in the region of the action potential (magenta, •). A region of membrane in its relative refractory period (yellow, ••) trails the action potential and prevents the nerve signal from going backward toward the cell body. The other membrane areas (green, •••) are fully polarized and ready to respond. **APR**

fuse. Neither does it get any stronger with distance, since each action potential is an all-or-none event.

Myelinated Axons and Saltatory Conduction

Myelinated fibers conduct signals in a very different manner called **saltatory²⁷ conduction**—meaning “leaping” or “jumping.” These axons cannot conduct a signal in continuous mode, like a burning fuse, because voltage-gated ion channels are too scarce in the myelin-covered internodal segments—fewer than 25/ μm^2 in these regions compared with 2,000 to 12,000/ μm^2 at the myelin sheath gaps (nodes of Ranvier). There would be little point in having ion channels in the internodal segments anyway—myelin insulates the axon from the ECF in these segments, and Na^+ from the ECF couldn't flow into the cell even if more channels were present. Therefore, no action potentials can occur in the internodal segments, and the nerve signal requires some other way of traversing the distance from one node to the next.

When Na^+ enters the axon at a node, it diffuses for a short distance along the inner face of the membrane (**fig. 12.18a**). Each sodium ion has an electrical field around it. When one Na^+ moves toward another, its field repels the other ion, which moves slightly and repels another, and so forth—like two magnets that repel each

²⁷from *saltare* = to leap, to dance

FIGURE 12.18 Saltatory Conduction of a Nerve Signal in a Myelinated Axon. (a) Sodium inflow at myelin sheath gaps, regenerating the flow of positive charges at each gap. (b) Action potentials (red, •) can occur only at myelin sheath gaps, so the nerve signal appears as if it were jumping from gap to gap. The membrane (yellow, ••) behind each action potential is temporarily in the refractive state, whereas the membrane (green, •••) ahead of it is fully excitable and ready for action.

other if you try to push their north poles together. No one ion moves very far, but this energy transfer travels down the axon much faster and farther than any of the individual ions. The signal grows weaker with distance, however, partly because the axoplasm resists the movement of the ions and partly because Na⁺ leaks back out of the axon along the way. Therefore, with distance, there is a lower and lower concentration of Na⁺ to relay the charge. Furthermore, with a surplus of positive charges on the inner face of the axolemma and a surplus of negative charges on the outer face, these cations and

anions are attracted to each other through the membrane—like the opposite poles of two magnets attracting each other through a sheet of paper. This results in a “storage” (called *capacitance*) of unmoving or sluggishly moving charges on the membrane.

Myelin speeds up signal conduction in two ways. First of all, by wrapping tightly around the axon, it seals it and greatly increases its resistance to the outward leakage of Na⁺. Sodium ions therefore maintain a higher density on the inner face of the membrane and transfer energy from one to another more rapidly. Second, myelin creates a greater

separation between the ICF and ECF. Cations and anions of the ICF and ECF are therefore less attracted to each other—like two magnets now separated by a thick sheet of cardboard. Na^+ ions can therefore move more freely within the axon, transferring energy from one to another.

A signal propagated in the foregoing manner can't travel much farther than 1 mm before it becomes too weak to open any voltage-gated Na^+ channels. But fortunately, there is another node (gap) every millimeter or less along the axon, where the axolemma is exposed to ECF and there is an abundance of voltage-gated channels. When the internodal signal reaches this point, it's just strong enough to open these channels, admit more Na^+ , and create a new action potential. This action potential has the same strength as the one at the previous node, so each node boosts the signal back to its original strength (+35 mV). However, the generation of action potentials is a relatively time-consuming process that slows down the nerve signal at the nodes.

Since action potentials occur only at the nodes, this mode of conduction creates a false impression that the nerve signal jumps from node to node (**fig. 12.18b**)—hence the expression *saltatory*.

You could think of saltatory conduction by analogy to a crowded subway car. The doors open (like the Na^+ gates at a node), 20 more people get on (like Na^+ flowing into the axon), and everyone has to push to the rear of the car to make room for them. No one passenger moves all the way from the door to the rear, but the crowding and transfer of energy from person to person forces even those at the rear to move a little, like the sodium ions at the next node. Events at one node thus create excitation at the next node some distance away.

In summary, saltatory conduction is based on a process that is very fast in the internodal segments (transfer of energy from ion to ion), but decremental. In the nodes, conduction is slower but nondecremental. Since most of the axon is covered with myelin, conduction occurs mainly by the fast internodal process. This is why myelinated axons conduct signals much faster (up to 120 m/s) than unmyelinated ones (up to 2 m/s).

▶▶▶ APPLY WHAT YOU KNOW

You are about to have a dental procedure and the dentist “numbs you up” with an injection of lidocaine (Xylocaine). This is a local anesthetic that prevents voltage-gated Na^+ channels from opening. Explain why this mechanism would block the conduction of pain signals from your teeth to your brain.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

11. What causes K^+ to diffuse out of a resting cell? What attracts it into the cell?
12. What happens to Na^+ when a neuron is stimulated on its dendrite? Why does the movement of Na^+ raise the voltage on the plasma membrane?
13. What does it mean to say a local potential is graded, decremental, and reversible?
14. How does the plasma membrane at the trigger zone differ from that on the cell body? How does it resemble the membrane at a myelin sheath gap?

15. What makes an action potential rise to +35 mV? What makes it drop again after this peak?
16. List four ways in which an action potential is different from a local potential.
17. Explain why myelinated axons conduct signals much faster than unmyelinated axons.

12.5 Synapses

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain how messages are transmitted from one neuron to another;
- b. give examples of neurotransmitters and neuromodulators and describe their actions; and
- c. explain how stimulation of a postsynaptic cell is stopped.

All good things must come to an end; a chain of action potentials soon reaches the end of an axon and can't go any farther. The point where a nerve ending (axon terminal) meets the next cell in line is called a **synapse**.²⁸ The next cell may be another neuron, a gland cell, a muscle cell, or a few other types. The most accessible and extensively studied type of synapse is the *neuromuscular junction (NMJ)* described in the previous chapter (section 11.3b). The most abundant synapses though, especially in the brain and spinal cord, are neuron-to-neuron synapses. It's to these we now turn our attention.

At these synapses, with respect to the direction of information flow, a signal arrives by way of the **presynaptic neuron**, which releases a neurotransmitter like the acetylcholine of the NMJ. The next neuron, which responds to it, is called the **postsynaptic neuron** (**fig. 12.19a**).

(a)

(b)

FIGURE 12.19 Synaptic Relationships Between Neurons.

(a) Pre- and postsynaptic neurons. (b) Types of synapses defined by the site of contact on the postsynaptic neuron.

FIGURE 12.20 Synapses. (a) Axon terminals synapsing with the cell body of a neuron in the sea slug, *Aplysia* (SEM). (b) Axon terminal synapsing with the dendrite of another neuron (TEM).

a: Omikron/Science Source/Getty Images; **b:** DENNIS KUNKEL MICROSCOPY/Science Source

A presynaptic neuron may synapse with a dendrite, the cell body (soma), or the axon of a postsynaptic neuron, forming an *axodendritic*, *axosomatic*, or *axoaxonic synapse*, respectively (**fig. 12.19b**). A neuron can have an enormous number of synapses (**fig. 12.20a**). For example, a spinal motor neuron is covered with about 10,000 axon terminals from other neurons—8,000 ending on its dendrites and another 2,000 on the cell body. In a part of the brain called the cerebellum, one neuron can have as many as 100,000 synapses.

12.5a The Discovery of Neurotransmitters

In the early twentieth century, biologists assumed that synaptic communication was electrical—a logical hypothesis given that neurons seemed to touch each other and signals were transmitted so quickly from one to the next. Cajal’s careful histological examinations, however, revealed a gap (*synaptic cleft*) between neurons, casting doubt on the possibility of electrical transmission. Cajal was rudely criticized for such a “preposterous” idea, but he was eventually proved correct.

In 1921, German pharmacologist Otto Loewi conclusively demonstrated that neurons communicate by releasing chemicals. The *vagus nerves* supply the heart, among other organs, and slow it down. Loewi opened two frogs and flooded the hearts with saline to keep them moist. He stimulated the vagus nerve of one frog, and

its heart rate dropped as expected. He then removed saline from that heart and squirted it onto the heart of the second frog. The solution alone reduced that frog’s heart rate. Evidently it contained something released by the vagus nerve of the first frog. Loewi had discovered what we now call acetylcholine—the first known neurotransmitter.

▶▶▶ APPLY WHAT YOU KNOW

As described, does the previous experiment conclusively prove that the second frog’s heart slowed as a result of something released by the vagus nerves? If you were Loewi, what control experiment would you do to rule out alternative hypotheses?

Following Loewi’s work, the idea of electrical communication between cells fell into disrepute. Now, however, we realize that some neurons, neuroglia, and cardiac and unitary smooth muscle do indeed have **electrical synapses**, where adjacent cells are joined by gap junctions and ions diffuse directly from one cell into the next. These junctions have the advantage of quick transmission because there is no delay for the release and binding of neurotransmitter. They are important in synchronizing the activity of local suites of neurons in certain regions of the brain. Their disadvantage, however, is that they can’t integrate information and make decisions. The ability to do that is a property of **chemical synapses**, in which neurons communicate by neurotransmitters. Chemical synapses are also the site of learning and memory, the target of many prescription drugs, and the site of action of drugs of addiction, among other things.

12.5b Structure of a Chemical Synapse

Where one neuron meets another, there is a gap called the **synaptic cleft** between the two cells. Typically about 20 nm wide, it is barely twice the width of a single cell membrane (**fig. 12.20b**). The gap is usually exaggerated in drawings of synapses like **figure 12.21** to allow space for showing events in synaptic signaling. Each neuron has proteins called **cell-adhesion molecules (CAMs)** in its membrane, which reach into the synaptic cleft and link to the CAMs of the other cell, like the cells holding hands with each other. CAMs prevent the two neurons from falling apart at the synapse and hold them in proper alignment for the release and receipt of the neurotransmitter.

Neurotransmitters are stored in bubbles called **synaptic vesicles** in the presynaptic axon terminal. Some of the vesicles are “docked” at release sites in the **active zone** of the presynaptic plasma membrane, ready to release neurotransmitter on demand. A reserve pool of synaptic vesicles stands ready a little farther from the cell surface, tethered to the cytoskeleton, ready to step forward and release their neurotransmitter into the cleft after the first group.

Directly across from the release sites, the receiving neuron has a **postsynaptic density** with a high concentration of neurotransmitter receptors and ion channels, especially on its dendrites and cell body. These are the means by which it receives and responds to the neurotransmitters. It was long thought that dendrites don’t release neurotransmitters but only receive them. It is now known, however, that they sometimes possess synaptic vesicles, release a variety of neurotransmitters of their own, and “talk back” to the presynaptic neurons. Thus, many chemical synapses are two-way paths of communication. This talk-back is called *retrograde* (“backward”) *signaling*.

FIGURE 12.21 Structure of a Chemical Synapse.

12.5c Neurotransmitters and Related Messengers

More than 100 neurotransmitters have been identified since Loewi's time. Neurotransmitters can be defined as molecules that are synthesized by a neuron, released when a nerve signal reaches an axon terminal, and have a specific effect on a receiving cell's physiology. Most of them are small organic molecules that are released by exocytosis and bind to specific receptors on the receiving cell, but there are exceptions. Some of the best-known neurotransmitters are listed in **table 12.3**. As you learn about parts of the brain in chapter 14, you may wish to refer back to this table to enhance your understanding of brain function. Most neurotransmitters fall into the following categories (**fig. 12.22**).

1. **Acetylcholine** is in a class by itself. It is formed from acetic acid (acetate) and choline.
2. **Amino acid** neurotransmitters include glycine, glutamate, aspartate, and γ -aminobutyric acid (GABA).
3. **Monoamines (biogenic amines)** are synthesized from amino acids by removal of the $-\text{COOH}$ group. They retain the $-\text{NH}_2$ (amino group), hence their name. Some monoamine neurotransmitters are epinephrine, norepinephrine, dopamine, serotonin (5-hydroxytryptamine,

or 5-HT), and histamine. The first three of these are in a subclass called **catecholamines** (CAT-eh-COAL-uh-meens).

4. **Purines** serving as neurotransmitters include adenosine and ATP (adenosine triphosphate).
5. **Gases**, specifically nitric oxide (NO) and carbon monoxide (CO), are inorganic exceptions to the usual definition of neurotransmitters. They're synthesized as needed rather than stored in synaptic vesicles; they simply diffuse out of the axon terminal rather than being released by exocytosis; and they diffuse into the receiving neuron rather than bind to a surface receptor.
6. **Neuropeptides** are chains of 2 to 40 amino acids. Some examples are cholecystokinin (CCK) and endorphins. Neuropeptides are stored in *secretory granules (dense-core vesicles)* about 100 nm in diameter, twice as large as typical synaptic vesicles. Some neuropeptides also function as hormones or as *neuromodulators* (see section 12.5f). Some are produced not only by neurons but also by the digestive tract; thus, they are known as *gut-brain peptides*. Some of these cause cravings for specific nutrients such as fat, protein, or carbohydrates (see chapter 26) and may be associated with certain eating disorders.

TABLE 12.3 Neurotransmitters (Selected Examples)

Name	Locations and Actions
Acetylcholine (ACh)	Neuromuscular junctions, most synapses of autonomic nervous system, retina, and many parts of the brain; excites skeletal muscle, inhibits cardiac muscle, and has excitatory or inhibitory effects on smooth muscle and glands depending on location
Amino Acids	
Glutamate	Cerebral cortex and brainstem; accounts for about 75% of all excitatory synaptic transmission in the brain; involved in learning and memory
Aspartate	Spinal cord; effects similar to those of glutamate
Glycine	Inhibitory neurons of the brain, spinal cord, and retina; most common inhibitory neurotransmitter in the spinal cord
GABA	Thalamus, hypothalamus, cerebellum, occipital lobes of cerebrum, and retina; the most common inhibitory neurotransmitter in the brain
Monoamines	
Norepinephrine	Sympathetic nervous system, cerebral cortex, hypothalamus, brainstem, cerebellum, and spinal cord; involved in dreaming, waking, and mood; excites cardiac muscle; can excite or inhibit smooth muscle and glands depending on location
Epinephrine	Hypothalamus, thalamus, spinal cord, and adrenal medulla; effects similar to those of norepinephrine
Dopamine	Hypothalamus, limbic system, cerebral cortex, and retina; highly concentrated in substantia nigra of midbrain; involved in elevation of mood and control of skeletal muscles
Serotonin	Hypothalamus, limbic system, cerebellum, retina, and spinal cord; also secreted by blood platelets and intestinal cells; involved in sleepiness, alertness, thermoregulation, mood, and behavior; over 95% of the body's serotonin is made by intestinal bacteria
Histamine	Hypothalamus; also a potent vasodilator released by mast cells of connective tissue and basophils of the blood
Neuropeptides	
Substance P	Basal nuclei, midbrain, hypothalamus, cerebral cortex, small intestine, and pain-receptor neurons; mediates pain transmission
Enkephalins	Hypothalamus, limbic system, pituitary, pain pathways of spinal cord, and nerve endings of digestive tract; act as analgesics (pain relievers) by inhibiting substance P; inhibit intestinal motility; modulate immune responses
β -endorphin	Digestive tract, spinal cord, and many parts of the brain; also secreted as a hormone by the pituitary; suppresses pain; secretion rises sharply during labor and delivery and in response to other pain situations
Cholecystokinin	Cerebral cortex and small intestine; suppresses appetite

FIGURE 12.22 Classification of Some Neurotransmitters. The neuropeptides are chains of amino acids, each identified by its three-letter code. Appendix D explains the codes.

▶▶▶ APPLY WHAT YOU KNOW

Unlike other neurotransmitters, neuropeptides can be synthesized only in the nerve cell body and must be transported to the axon terminals. Why is their synthesis limited to the cell body?

We will see, especially in chapter 15, that a given neurotransmitter doesn't have the same effect everywhere in the body. There are multiple receptor types in the body for a particular neurotransmitter—at least 14 receptor types for serotonin, for example—and it is the receptor that governs what effect a neurotransmitter has on its target cell. Most human and other mammalian neurons can secrete two or more neurotransmitters and can switch from one to another under different circumstances.

12.5d Synaptic Transmission

Some neurotransmitters are excitatory, some are inhibitory, and for some the effect depends on what kind of receptor the postsynaptic cell has. Some open ligand-gated ion channels and others act through second messengers. Bearing this diversity in mind, we'll examine three kinds of synapses with different modes of action.

An Excitatory Cholinergic Synapse

A **cholinergic**²⁹ (CO-lin-UR-jic) synapse employs acetylcholine (ACh) as its neurotransmitter. ACh excites some postsynaptic cells (such as skeletal muscle) and inhibits others (such as cardiac muscle), but this discussion will describe an excitatory action. The steps in transmission at such a synapse are as follows (fig. 12.23):

- 1 The arrival of a nerve signal at the axon terminal opens voltage-gated calcium channels.
- 2 Ca^{2+} enters the terminal and triggers exocytosis of the synaptic vesicles, releasing ACh.
- 3 Empty vesicles drop back into the cytoplasm to be refilled with ACh, while synaptic vesicles in the reserve pool move to the active sites and release their ACh—a bit like a line of Revolutionary War soldiers firing their muskets and falling back to reload as another line moves to the fore.
- 4 Meanwhile, ACh diffuses across the synaptic cleft and binds to ligand-gated channels on the postsynaptic neuron. These channels open, allowing Na^+ to enter the cell and K^+ to leave. Although illustrated separately, Na^+ and K^+ pass in opposite directions through the same gates.
- 5 As Na^+ enters, it spreads out along the inside of the plasma membrane and depolarizes it, producing a local voltage shift called the **postsynaptic potential**. Like other local potentials, if this is strong and persistent enough (that is, if enough current makes it to the axon hillock), it opens voltage-gated ion channels in the trigger zone and causes the postsynaptic neuron to fire.

²⁹cholin = acetylcholine; erg = work, action

FIGURE 12.23 Transmission at a Cholinergic Synapse. Acetylcholine directly opens ion channels in the plasma membrane of the postsynaptic neuron. Numbered steps 1 through 5 correspond to the description in the adjacent text. Steps 6 through 8 pertain to cessation of the signal (section 12.5e). **APR**

Steps 6 through 8 in figure 12.23 concern the mechanism for halting transmission and are explained shortly.

An Inhibitory GABA-ergic Synapse

Synapses that employ γ -aminobutyric acid (GABA) as their neurotransmitter are called **GABA-ergic synapses**. Amino acid neurotransmitters such as GABA work by the same mechanism as ACh; they bind to ion channels and cause immediate changes in membrane potential. The release of GABA and binding to its receptor are similar to the preceding case. The GABA receptor, however, is a chloride channel. When it opens, Cl^- enters the cell and makes the inside even more negative than the resting membrane potential. The neuron is therefore inhibited, or less likely to fire.

An Excitatory Adrenergic Synapse

An **adrenergic synapse** employs the neurotransmitter norepinephrine (NE), also called noradrenaline. NE, other monoamines, and neuropeptides act through second messengers such as cyclic AMP (cAMP).

FIGURE 12.24 Transmission at an Adrenergic Synapse. Numbered steps correspond to the description in nearby text.

The receptor is not an ion channel but a transmembrane protein associated with a G protein on the inner face of the membrane. **Figure 12.24** shows some ways in which an adrenergic synapse can function, numbered to correspond to the following:

- ① The unstimulated NE receptor is bound to a G protein.
- ② Binding of NE to the receptor causes the G protein to dissociate from it.
- ③ The G protein binds to adenylate cyclase and activates this enzyme, which converts ATP to cAMP.
- ④ Cyclic AMP can induce several alternative effects in the cell.
- ⑤ One effect is to produce an internal chemical that binds to a ligand-gated ion channel from the inside, opening the channel and depolarizing the cell.
- ⑥ Another is to activate preexisting cytoplasmic enzymes, which can lead to diverse metabolic changes (for example, inducing a liver cell to break down glycogen and release glucose into the blood).

- ⑦ Yet another is for cAMP to induce genetic transcription, so that the cell produces new enzymes leading to diverse metabolic effects.

Although slower to respond than cholinergic and GABA-ergic synapses, adrenergic synapses do have an advantage—**signal amplification**. A single NE molecule binding to a receptor can induce the formation of many cAMPs, each of those can activate many enzyme molecules or induce the transcription of a gene to generate numerous mRNA molecules, and each of those can result in the production of a vast number of enzyme molecules and metabolic products such as glucose molecules.

As complex as synaptic events may seem, they typically require only 0.5 ms or so—an interval called **synaptic delay**. This is the time from the arrival of a signal at the axon terminal of a presynaptic cell to the beginning of an action potential in the postsynaptic cell.

12.5e Cessation of the Signal

It is important not only to stimulate a postsynaptic cell but also to turn off the stimulus in due time. Otherwise the postsynaptic neuron could continue firing indefinitely, causing a breakdown in physiological coordination. But a neurotransmitter molecule binds to its receptor for only 1 ms or so, then dissociates from it. If the presynaptic cell continues to release neurotransmitter, one molecule is quickly replaced by another and the postsynaptic cell is restimulated. This immediately suggests a way of stopping synaptic transmission—stop adding new neurotransmitter and get rid of that which is already there. The first step is achieved simply by the cessation of signals in the presynaptic neuron. The second can be achieved in the following ways, pictured as steps 6 to 8 in figure 12.23:

- ⑥ **Neurotransmitter degradation.** An enzyme in the synaptic cleft breaks the neurotransmitter down into fragments that have no stimulatory effect on the postsynaptic cell. Depicted here is acetylcholinesterase (AChE) breaking ACh down into choline and acetate.
- ⑦ **Reuptake.** A neurotransmitter or its breakdown products are reabsorbed by transport proteins in the axon terminal, removing them from the synapse and ending their stimulatory effect. Choline from ACh is recycled to make new ACh. Amino acid and monoamine neurotransmitters are similarly reabsorbed, then broken down within the axon terminal by an enzyme called **monoamine oxidase (MAO)**. Some antidepressant drugs work by inhibiting MAO. Some cases of autism, attention-deficit/hyperactivity disorder (ADHD), parkinsonism, and depression stem from mutations that impair the function of some of these transport proteins. The reuptake process is targeted by some drugs for these disorders.
- ⑧ **Diffusion.** Neurotransmitters or their breakdown products simply diffuse away from the synapse into the nearby extracellular fluid. As shown in figure 12.23, this is what happens to the acetate component of ACh, but in other cases, the neurotransmitter escapes the synapse intact. In the CNS, astrocytes absorb stray neurotransmitters and return them to the presynaptic neurons. In ganglia of the PNS, it seems that the satellite cells that surround neurons perform this role; this is an area of current scientific investigation.

12.5f Neuromodulators

Neurons sometimes secrete chemical signals with long-term effects on entire groups of neurons instead of brief, quick effects at an individual synapse. Some call these **neuromodulators** to distinguish them from neurotransmitters; others use the term *neurotransmitter* broadly to include them. Neuromodulators adjust, or *modulate*, the activity of neuron groups in various ways: increasing the release of neurotransmitters by presynaptic neurons; adjusting the sensitivity of postsynaptic neurons to neurotransmitters; or altering the rate of neurotransmitter reuptake or breakdown to prolong their effects.

The simplest neuromodulator is the gas **nitric oxide (NO)**. NO diffuses readily into a postsynaptic cell and activates second-messenger pathways with such effects as relaxing smooth muscle. This has the effect of dilating small arteries and increasing blood flow to a tissue; this is the basis for the action of drugs for erectile dysfunction (see Deeper Insight 27.4). The neuropeptides are neuromodulators; among these are the **enkephalins** and **endorphins**, which inhibit spinal neurons from transmitting pain signals to the brain. Other neuromodulators include hormones and some neurotransmitters such as dopamine, serotonin, and histamine. The last point may seem confusing, but the terms *neurotransmitter*, *hormone*, and *neuromodulator* define not so much the chemical itself, but the role it plays in a given context. One chemical can play two or more of these roles in different places and circumstances.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

18. Concisely describe five steps that occur between the arrival of an action potential at the axon terminal and the beginning of a new action potential in the postsynaptic neuron.
19. Contrast the actions of acetylcholine, GABA, and norepinephrine at their respective synapses.
20. Describe three mechanisms that stop synaptic transmission.
21. What is the function of neuromodulators? Compare and contrast neuromodulators and neurotransmitters.

12.6 Neural Integration

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain how a neuron “decides” whether or not to generate action potentials;
- b. explain how the nervous system translates complex information into a simple code;
- c. explain how neurons work together in groups to process information and produce effective output; and
- d. describe how memory works at the cellular and molecular levels.

Synaptic delay slows the transmission of nerve signals; the more synapses there are in a neural pathway, the longer it takes

information to get from its origin to its destination. You may wonder, therefore, why we have synapses—why a nervous pathway isn’t, indeed, a continuous “wire” as biologists believed before Cajal. The presence of synapses isn’t due to limitations on axon length—after all, one axon can reach from your toes to your brainstem. We also have seen that cells communicate more quickly through gap junctions than through chemical synapses. So why have chemical synapses at all?

What we value most about our nervous system is its ability to process information, store it, and make decisions—and chemical synapses are the decision-making devices of the system. The more synapses a neuron has, the greater its information-processing capability. At this moment, you are using certain *pyramidal cells* of the cerebral cortex (see this chapter’s opening photo) to read and comprehend this passage. Each pyramidal cell has about 40,000 synaptic contacts with other neurons. The cerebral cortex alone (the main information-processing tissue of your brain) is estimated to have 100 trillion (10^{14}) synapses. To get some impression of this number, imagine trying to count them. Even if you could count two synapses per second, day and night without stopping, and you were immortal, it would take you 1.6 million years. The ability of your neurons to process information, store and recall it, and make decisions is called **neural integration**.

12.6a Postsynaptic Potentials

Neural integration is based on the postsynaptic potentials produced by neurotransmitters. Remember that a typical neuron has a resting membrane potential (RMP) of about -70 mV and a threshold of about -55 mV. A neuron has to be depolarized to this threshold in order to produce action potentials. Any voltage change in that direction makes a neuron more likely to fire and is therefore called an **excitatory postsynaptic potential (EPSP)** (fig. 12.25a). EPSPs usually result from Na^+ flowing into the cell and neutralizing some of the negative charge on the inside of the membrane.

In other cases, a neurotransmitter hyperpolarizes the postsynaptic cell and makes it more negative than the RMP. Since this makes the postsynaptic cell less likely to fire, it is called an **inhibitory postsynaptic potential (IPSP)** (fig. 12.25b). Some IPSPs are produced by a neurotransmitter opening ligand-gated chloride channels, causing Cl^- to flow into the cell and make the cytosol more negative. A less common way is to open selective K^+ channels, increasing K^+ diffusion out of the cell.

We must recognize that because of ion leakage through their membranes, all neurons fire at a certain background rate even when they aren’t being stimulated. EPSPs and IPSPs don’t determine whether or not a neuron fires, but only change the rate of firing by stimulating or inhibiting the production of more action potentials.

Glutamate and aspartate are excitatory brain neurotransmitters that produce EPSPs. Glycine and GABA produce IPSPs and are therefore inhibitory. Acetylcholine (ACh) and norepinephrine are excitatory to some cells and inhibitory to others, depending on the type of receptors present. For example, ACh excites skeletal muscle but inhibits cardiac muscle because of different types of ACh receptors.

FIGURE 12.25 Postsynaptic Potentials. (a) An excitatory postsynaptic potential (EPSP), which shifts the membrane voltage closer to threshold and makes the cell more likely to fire. (b) An inhibitory postsynaptic potential (IPSP), which shifts the membrane voltage farther away from threshold and makes the cell less likely to fire. The sizes of these postsynaptic potentials are greatly exaggerated here for clarity; compare figure 12.27.

? Why is a single EPSP insufficient to make a neuron fire?

12.6b Summation, Facilitation, and Inhibition

One neuron may receive input from thousands of other neurons. Some incoming axons may produce EPSPs while others produce IPSPs. The neuron's response depends on whether the *net* input is excitatory or inhibitory. If EPSPs override the IPSPs, threshold may be reached and set off an action potential; if IPSPs prevail, they inhibit the neuron from firing. **Summation** is the process of adding up postsynaptic potentials and responding to their net effect. It occurs in the trigger zone.

Suppose, for example, you're working in the kitchen and accidentally touch a hot pot. EPSPs in your motor neurons might cause you to jerk your hand back quickly and avoid being burned. Yet a moment later, you might nonchalantly sip a cup of hot tea. Since you're expecting it to be hot, you don't jerk it away from your lips. You have learned that it won't injure you, so at some level of the nervous system, IPSPs prevail and inhibit the motor response.

FIGURE 12.26 Temporal and Spatial Summation. Vertical lines on the axons indicate relative firing frequency. Arrows within the postsynaptic neuron indicate the path of local graded potentials. (a) Temporal summation resulting from rapid firing of a single presynaptic neuron. (b) Spatial summation as an additive effect of multiple presynaptic neurons firing at moderate rates.

It is fundamentally a balance between EPSPs and IPSPs that enables the nervous system to make decisions. A postsynaptic neuron is like a little cellular democracy acting on the “majority vote” of hundreds or thousands of presynaptic cells. In the tea example, some presynaptic neurons send messages that signify “Hot! Danger!” in the form of EPSPs that may activate a hand-withdrawal reflex, while at the same time, others produce IPSPs that signify “Safe” and suppress the reflex. Whether you jerk your hand away depends on whether the EPSPs override the IPSPs or vice versa.

Weak stimulation of a postsynaptic neuron may generate an EPSP, but it fades before reaching threshold. A typical EPSP is a voltage change of only 0.5 mV and lasts only 15 to 20 ms. If a neuron has an RMP of -70 mV and a threshold of -55 mV, it needs at least 30 EPSPs to reach threshold and fire. There are two ways in which EPSPs can add up to do this, and both may occur simultaneously.

1. **Temporal summation (fig. 12.26a).** This occurs when a single synapse generates EPSPs so quickly that each is generated before the previous one fades out. This allows the EPSPs to add up over time to a threshold voltage that triggers an action potential (fig. 12.27). Temporal summation can occur if even one presynaptic neuron stimulates the postsynaptic neuron at a fast enough rate.
2. **Spatial summation (fig. 12.26b).** This occurs when EPSPs from several synapses add up to threshold at the axon

FIGURE 12.27 Summation of EPSPs. Each stimulus (arrow) produces one EPSP. If enough EPSPs arrive at the trigger zone faster than they fade, they can build on each other to bring the neuron to threshold and trigger an action potential.

hillock. Any one synapse may generate only a weak signal, but several synapses acting together can bring the hillock to threshold. The presynaptic neurons collaborate to induce the postsynaptic neuron to fire.

Neurons routinely work in groups to modify each other's actions. **Presynaptic facilitation** is a process in which one neuron enhances the effect of another. **Figure 12.28** depicts such an interaction between

three neurons we will call neuron F for a facilitating neuron, S for a stimulating neuron, and R for a responding neuron. Neuron F forms an axoaxonic synapse with the axon terminal of neuron S. When neuron F is quiescent, neuron S shows only a low level of activity, releasing some neurotransmitter but not necessarily enough to excite neuron R to threshold. But if circumstances call for enhancing information transmission across synapse S-R, neuron F can release a neurotransmitter such as serotonin. Serotonin makes voltage-gated calcium channels in the axon terminal of S remain open longer. Increased calcium inflow increases neurotransmitter release by S, which now excites neuron R. The facilitating neuron F thus accentuates synaptic transmission.

The spatial summation seen in figure 12.26b is another way of facilitating the firing of a postsynaptic neuron. One neuron acting alone may be unable to induce a postsynaptic neuron to fire, but when they collaborate, their combined “effort” does induce firing in the postsynaptic cell.

Presynaptic inhibition is the opposite of facilitation, a mechanism in which one presynaptic neuron suppresses another one. This mechanism is used to reduce or halt unwanted synaptic transmission. In **figure 12.29**, we see another three neurons in which the facilitating neuron is replaced by an inhibitory neuron, I. When neuron I is silent, neuron S releases its neurotransmitter and triggers a response in R. But when there is a need to block transmission across this pathway, neuron I releases the inhibitory neurotransmitter GABA. GABA prevents the voltage-gated calcium channels of neuron S from opening. Consequently, neuron S releases less neurotransmitter or none, and fails to stimulate neuron R.

12.6c Neural Coding

The nervous system must interpret and pass along both quantitative and qualitative information about its environment—whether a light is dim or bright, red or green; whether a taste is mild or intense, salty or sour; whether a sound is loud or soft, high-pitched or low.

FIGURE 12.28 Presynaptic Facilitation. F, facilitating neuron; S, stimulating neuron; R, responding postsynaptic neuron; +, excitation (EPSP). (a) Inactivity of neuron R owing to absence of stimulation by neuron F. (b) Activity in neuron R owing to stimulation (facilitation) of the S-R synapse by neuron F.

FIGURE 12.29 Presynaptic Inhibition. S, stimulating neuron; I, inhibitory neuron; R, responding postsynaptic neuron; +, excitation (EPSP); –, inhibition (IPSP). (a) Activity in the S-R synapse in the absence of inhibition by neuron I. (b) Activity of neuron I inhibiting synaptic transmission between S and R.

Considering the complexity of information to be communicated about conditions in and around the body, it seems a marvel that it can be done in the form of something as simple as action potentials—particularly since all the action potentials of a given neuron are essentially identical. Yet when we considered the genetic code in chapter 4, we saw that complex messages can indeed be expressed in simple codes. The way in which the nervous system converts information to a meaningful pattern of action potentials is called **neural coding** (or *sensory coding* when it occurs in the sense organs).

The most important mechanism for transmitting qualitative information is the **labeled line code**. This code is based on the fact that each nerve fiber to the brain leads from a receptor that specifically recognizes a particular stimulus type. Nerve fibers in the optic nerve, for example, carry signals only from light receptors in the eye; these fibers never carry information about taste or sound. The brain therefore interprets any signals in those fibers in terms of light—even if the signals result from artificial stimulation of the nerve. This effect is seen when you rub your eyelids and see flashes of light as the pressure on the eyeball mechanically stimulates optic nerve fibers. Electrical stimulation of the auditory nerve can enable deaf people to hear sounds of different frequencies, even when receptors in the inner ear are nonfunctional. Thus, each nerve fiber to the brain is a line of communication “labeled,” or recognized by the brain, as representing a particular stimulus quality—the color of a light, the pitch of a sound, or the salty or sour quality of a taste, for example.

Quantitative information—information about the intensity of a stimulus—is encoded in two ways. One depends on the fact that different neurons have different thresholds of excitation. A weak stimulus excites sensitive neurons with the lowest thresholds, while a strong stimulus excites less sensitive high-threshold neurons. Bringing additional neurons into play as the stimulus becomes stronger is called **recruitment**. It enables the nervous system to judge stimulus strength by which neurons, and how many of them, are firing.

Another way of encoding stimulus strength depends on the fact that the more strongly a neuron is stimulated, the more frequently it fires. A weak stimulus may cause a neuron to generate 6 action potentials per second, and a strong stimulus, 600 per second. Thus, the central nervous system can judge stimulus strength from the firing frequency of afferent neurons (**fig. 12.30**).

There is a limit to how often a neuron can fire, set by its absolute refractory period. By analogy, think of an old camera with an

FIGURE 12.30 An Example of Neural Coding. This figure is based on recordings made from a sensory fiber of the frog sciatic nerve as the gastrocnemius muscle was stretched by suspending weights from it. As the stimulus strength (weight) and stretch increase, the firing frequency of the neuron increases. Firing frequency is a coded message that informs the CNS of stimulus intensity.

? In what other way is the CNS informed of stimulus intensity?

electronic flash that takes 5 seconds to recharge after each photo. At best, one could take only 12 photos a minute with it. Similarly, if a nerve fiber takes 1 ms to repolarize after it has fired, then it can't fire more than 1,000 times per second. Refractory periods may be as short as 0.5 ms, which sets a theoretical limit to firing frequency of 2,000 action potentials per second. The highest frequencies actually observed, however, are 500 to 1,000 per second.

In summary, mild stimuli excite sensitive, low-threshold neurons. As the stimulus intensity rises, these neurons fire at a higher and higher frequency, up to a certain maximum. If the stimulus intensity exceeds the capacity of these low-threshold neurons, it may recruit less sensitive, high-threshold neurons to begin firing. Still further increases in intensity cause these high-threshold neurons to fire at a higher and higher frequency.

▶▶▶ APPLY WHAT YOU KNOW

How is neural recruitment related to the process of multiple motor unit summation (see section 11.5b)?

12.6d Neural Pools and Circuits

So far, we have dealt with interactions involving only two or three neurons at a time. Actually, neurons function in larger ensembles called **neural pools**, each of which may consist of thousands of interneurons concerned with a particular body function—one to control the rhythm of your breathing, one to move your limbs rhythmically as you walk, one to regulate your sense of hunger, and another to interpret smells, for example. At this point, we explore a few ways in which neural pools collectively process information.

Discharge and Facilitated Zones

Information arrives at a neural pool through one or more input neurons, which branch repeatedly and synapse with numerous interneurons in the pool. Some input neurons form multiple synapses with a single postsynaptic cell. They can produce EPSPs at all points of contact with that cell and, through spatial summation, make it fire more easily than if they synapsed with it at only one point. Within the **discharge zone** of an input neuron, that neuron acting alone can make the postsynaptic cell fire (**fig. 12.31**). But in a broader **facilitated zone**, it synapses with still other neurons in the pool, with fewer synapses on each of them. It can stimulate those neurons to fire only with the assistance of other input neurons; that is, it facilitates the others. It “has a vote” on what the postsynaptic cells in the facilitated zone will do, but it cannot determine the outcome by itself. Such arrangements, repeated thousands of times throughout the central nervous system, give neural pools great flexibility in integrating input from several sources and deciding on an appropriate output.

Types of Neural Circuits

The functioning of a radio can be understood from a circuit diagram showing its components and their connections. Similarly, the functions of a neural pool are partly determined by its **neural circuit**—the

FIGURE 12.31 Facilitated and Discharge Zones in a Neural Pool.

pathways among its neurons. Just as a wide variety of electronic devices are constructed from a relatively limited number of circuit types, a wide variety of neural functions result from the operation of four principal kinds of neural circuits (**fig. 12.32**):

1. In a **diverging circuit**, an individual neuron transmits signals to multiple downstream neurons, or one neural pool may transmit output to multiple downstream neural pools. Each of those neurons or neural pools may communicate with several more, so input from just one pathway may produce output through hundreds of others. Such a circuit allows signals from one motor neuron of the brain, for example, to ultimately stimulate thousands of muscle fibers.

FIGURE 12.32 Four Types of Neural Circuits. Arrows indicate the direction of the nerve signal.

? Which of these four circuits is likely to fire the longest after a stimulus ceases? Why?

2. A **converging circuit** is the opposite of a diverging circuit—input from many neurons or neural pools is funneled to fewer and fewer intermediate or output pathways. For example, you have a brainstem respiratory center that receives converging information from other parts of your brain, blood chemistry sensors in your arteries, and stretch receptors in your lungs. The respiratory center can then produce an output that takes all of these factors into account and sets an appropriate pattern of breathing.
3. In a **reverberating circuit**, neurons stimulate each other in a linear sequence from input to output neurons, but some of the neurons late in the path send axon collaterals back to neurons earlier in the path and restimulate them. As an exceedingly simplified model of such a circuit, consider a path such as $A \rightarrow B \rightarrow C \rightarrow D$, in which neuron C sends an axon collateral back to A. As a result, every time C fires it not only stimulates output neuron D, but also restimulates A and starts the process over. Such a circuit produces a prolonged or repetitive effect that lasts until one or more neurons in the circuit fail to fire, or an inhibitory signal from another source stops one of them from firing. A reverberating circuit sends repetitious signals to your diaphragm and intercostal muscles, for example, to make you inhale. Sustained output from the circuit ensures that the respiratory muscles contract for the 2 seconds or so that it normally takes to fill the lungs. When the circuit stops firing, you exhale; the next time it fires, you inhale again. Reverberating circuits may also be involved in short-term memory, as discussed in the next section, and they may play a role in the uncontrolled “storms” of neural activity that occur in epilepsy.
4. In a **parallel after-discharge** circuit, an input neuron diverges to stimulate several chains of neurons. Each chain has a different number of synapses, but eventually they all reconverge on one or a few output neurons. Since the chains differ in total synaptic delay, their signals arrive at the output neurons at different times, and the output neurons may go on firing for some time after input has ceased. Unlike a reverberating circuit, this type has no feedback loop. Once all the neurons in the circuit have fired, the output ceases. Continued firing after the stimulus stops is called *after-discharge*. It explains why you can stare at a lamp, then close your eyes and continue to see an image of it for a while. Such a circuit is also important in withdrawal reflexes, in which a brief pain produces a longer-lasting output to the limb muscles and causes you to draw back your hand or foot from danger.

Serial and Parallel Processing

In relation to these circuit types, the nervous system handles information in two modes called serial and parallel processing. In **serial processing**, neurons and neural pools relay information along a pathway in a relatively simple linear fashion and can process only one flow of information at a time. For example, you can read your e-mail or listen to a class lecture, and the language recognition centers of your brain can process one linguistic input or the other; however, you can't do both simultaneously. To understand the

e-mail, you have to stop paying attention to the lecture; to understand the lecture, you have to stop checking your e-mail. You may jump back and forth between one and the other, only half understanding each, but you can't simultaneously process the written message in an e-mail and the spoken language of the lecture. Each must be processed separately and serially.

In **parallel processing**, information is transmitted along diverging circuits through different pathways that act on it simultaneously, to different purposes. For example, when you're driving your car, your visual system (eye and brain) must simultaneously process information about color, shape, depth of field, and motion in the scene before your eyes. This requires complex parallel processing circuits from the retinas of your eyes through the visual centers at the rear of your brain. At the same time, you must process traffic sounds and signals from your body's own joint and motion sensors to know, for example, how hard you are pressing the gas or brake pedal. Efficient simultaneous processing of such information is crucial to your own ability to drive safely.

Serial and parallel processing certainly occur as well in innumerable unconscious processes much simpler than the foregoing examples. In chapter 13, you should be able to see how they apply to certain spinal reflexes.

12.6e Memory and Synaptic Plasticity

You may have wondered as you studied this chapter, How am I going to remember all of this? It seems fitting that we end this chapter with the subject of how memory works, for you now have the information necessary to understand its cellular and chemical basis.

The things we learn and remember aren't stored in individual “memory cells” in the brain. You don't have a neuron assigned to remember your phone number and another to remember your grandmother's face, for example. Instead, the physical basis of memory is a *pathway* through the brain called a **memory trace (engram)**³⁰, in which new synapses have formed or existing synapses have been modified to make transmission easier. In other words, synapses aren't fixed for life; in response to experience, they can be added, taken away, or modified to make transmission easier or harder. Indeed, synapses can be created or deleted in as little as 1 or 2 hours. The ability of synapses to change is called **synaptic plasticity**.

Think about when you learned as a child to tie your shoes. You probably found the procedure slow, confusing, and laborious at first, but eventually it became so easy you could do it with little thought—like a motor program playing out in your brain without requiring your conscious attention. It became easier to do because the synapses in a certain pathway were modified to allow signals to travel more easily across them than across “untrained” synapses, thus creating your *motor memory* for the task. The process of making transmission easier is called **synaptic potentiation** (one form of synaptic plasticity).

Neuroscientists still argue about how to classify the various forms of memory, but three kinds often recognized are *immediate*

³⁰*en* = inner; *gram* = mark, trace, record

memory, short-term memory, and long-term memory. We also know of different modes of synaptic potentiation that last from just a few seconds to a lifetime, and we can correlate these at least tentatively with different forms of memory.

Immediate Memory

Immediate memory is the ability to hold something in mind for just a few seconds. By remembering what just happened, we get a feeling for the flow of events and a sense of the present. Immediate memory is indispensable to the ability to read; you must remember the earliest words of a sentence until you get to its end in order to extract any meaning from it. You couldn't make any sense of what you read if you forgot each word as soon as you moved on to the next one. Immediate memory may be based on reverberating circuits. Our impression of what just happened can thus echo in our minds for a few seconds as we experience the present moment and anticipate the next one.

Short-Term Memory

Short-term memory (STM) lasts from a few seconds to a few hours. Information stored in STM may be quickly forgotten if you stop mentally reciting it, you are distracted, or you have to remember something new. **Working memory** is a form of STM that allows you to hold an idea in mind long enough to carry out an action such as calling a telephone number you just looked up, working out the steps of a mathematics problem, or searching for a lost set of keys while remembering where you've already looked. It is limited to a few bits of information such as the digits of a telephone number. Evidence suggests that working memory resides in a circuit of facilitated synapses that remain quiescent (consuming little energy) most of the time, but are reactivated by new stimulation.

Making it easier to transmit signals across a synapse is called **synaptic facilitation** (different from the facilitation of one neuron by another that we studied earlier). Synaptic facilitation can be produced by *tetanic stimulation*, the rapid arrival of repetitive signals at a synapse. Each signal causes a certain amount of Ca^{2+} to enter the axon terminal. If signals arrive rapidly, the neuron can't pump out all the Ca^{2+} admitted by one action potential before the next action potential occurs. More and more Ca^{2+} accumulates in the terminal. Since Ca^{2+} is what triggers the release of neurotransmitter, each new signal releases more neurotransmitter than the one before. With more neurotransmitter, the EPSPs in the postsynaptic cell become stronger and stronger, and that cell is more likely to fire.

Memories lasting for a few hours, such as remembering what someone said to you earlier in the day or remembering an upcoming appointment, may involve **posttetanic potentiation**. In this process, the Ca^{2+} level in the axon terminal stays elevated for so long that another signal, coming well after the tetanic stimulation has ceased, releases an exceptionally large burst of neurotransmitter. That is, if a synapse has been heavily used in the recent past, a new stimulus can excite the postsynaptic cell more easily. Thus, your memory may need only a slight jog to recall something from several hours earlier.

Long-Term Memory

Long-term memory (LTM) lasts up to a lifetime and is less limited than STM in the amount of information it can store. LTM allows you to memorize the lines of a play, the words of a favorite song, or (one hopes!) textbook information for an exam. On a still longer timescale, it enables you to remember your name, the route to your home, and your childhood experiences.

There are two forms of long-term memory: explicit and implicit. **Explicit or declarative memory** is the retention of events and facts that you can put into words—numbers, names, dates, and so forth. You must think to remember these things. **Implicit memory** is the memory of things that come reflexively or unconsciously, including *emotional memories* (such as the fear of being stung if a wasp lands on you) and *procedural memory*, the retention of motor skills—how to tie your shoes, play a musical instrument, or type on a keyboard. These forms of memory involve different regions of the brain but are probably similar at the cellular level.

Some LTM involves the physical remodeling of synapses or the formation of new ones through the growth and branching of axon terminals and dendrites. In the pyramidal cells of the brain, the dendrites are studded with knoblike *dendritic spines* that increase the area of synaptic contact (see fig. 12.5a). Studies on fish and other experimental animals have shown that social and sensory deprivation causes these spines to decline in number, while a richly stimulatory environment causes them to proliferate—an intriguing clue to the importance of a stimulating environment to infant and child development. In some cases of LTM, a new synapse grows beside the original one, giving the presynaptic cell twice as much input into the postsynaptic cell.

LTM can also be grounded in molecular changes called **long-term potentiation (LTP)**. This involves *NMDA*³¹ *receptors*, which are glutamate-binding receptors found on the dendritic spines of pyramidal cells. NMDA receptors are usually blocked by magnesium ions (Mg^{2+}), but when they bind glutamate and are simultaneously subjected to high-frequency stimulation, they expel the Mg^{2+} and open to admit Ca^{2+} into the dendrite. When Ca^{2+} enters the pyramidal cells, it acts as a second messenger with multiple effects. A high Ca^{2+} level activates enzymes called *protein kinases*, which phosphorylate (add phosphate to) proteins employed in building and strengthening synapses. The neuron also produces even more NMDA receptors, making it more sensitive to glutamate, and it may send signals such as nitric oxide (NO) back to the presynaptic cell to enhance its release of neurotransmitter.

You can see that in all of these ways, long-term potentiation can increase transmission across “experienced” synapses. Remodeling a synapse or installing more neurotransmitter receptors has longer-lasting effects than facilitation or posttetanic potentiation.

³¹*N-methyl-D-aspartate*, a chemical similar to glutamate

How We Forget

Forgetting is arguably as important as remembering; we would likely be driven mad if we couldn't forget the myriad trivial things we encounter every day. People with a pathological inability to forget trivial information have great difficulty in reading comprehension and other functions that require us to distinguish what is important from what is not.

Immediate and short-term memories vanish simply as neural circuits cease to fire. Long-term memories can be erased by a process of **long-term depression (LTD)**. Low-frequency stimulation of a synapse results in low levels of intracellular Ca^{2+} . This activates *protein phosphatases*, which dephosphorylate synaptic proteins such as actin microfilaments that support dendritic spines. These proteins are then degraded by *proteasomes* (see fig. 3.31), which tear down dendritic spines and remove little-used synapses from the neural circuits.

The anatomical sites of memory in the brain are discussed in chapter 14. Regardless of the sites, however, the cellular mechanisms are as described here.

DEEPER INSIGHT 12.4

CLINICAL APPLICATION

Alzheimer and Parkinson Diseases

Alzheimer and Parkinson diseases are the two most common degenerative disorders of the brain. Both are associated with neurotransmitter deficiencies.

Alzheimer³² disease (AD) may begin before the age of 50 with signs so slight and ambiguous that early diagnosis is difficult. One of its first signs is memory loss, especially for recent events. A person with AD may ask the same questions repeatedly, show a reduced attention span, and become disoriented and lost in previously familiar places. Family members often feel helpless and confused as they watch their loved one's personality gradually deteriorate beyond recognition. The AD patient may become moody, confused, paranoid, combative, or hallucinatory. The patient may eventually lose even the ability to read, write, talk, walk, and eat. Death typically ensues from pneumonia or other complications of confinement and immobility.

AD affects about 11% of the U.S. population over the age of 65; the incidence rises to 47% by age 85. It accounts for nearly half of all nursing home admissions and is a leading cause of death among the elderly. AD claims about 100,000 lives per year in the United States.

Diagnosis of AD can be confirmed by autopsy. There is atrophy of some of the gyri (folds) of the cerebral cortex and the hippocampus, an important center of memory. Nerve cells exhibit *neurofibrillary tangles*—dense masses of broken and twisted cytoskeleton (**fig. 12.33**). Alois Alzheimer first observed these in 1907 in the brain of a patient who had died of senile dementia. The more severe the signs of disease, the more neurofibrillary tangles are seen at autopsy. In the intercellular spaces, there are *senile plaques* consisting of aggregations of cells, altered nerve fibers, and a core of *β -amyloid protein*—the breakdown product of a glycoprotein of plasma membranes. Amyloid protein is rarely seen in elderly people without AD. Oxidative stress (free radical injury) is now widely believed to underlie the formation of amyloid protein and neurofibrillary tangles, and all the other aspects of AD pathology. This has led to interest in whether

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

22. Contrast the two types of summation at a synapse and explain how they function in synaptic decision making.
23. Describe how the nervous system communicates quantitative and qualitative information about stimuli.
24. List the four types of neural circuits and describe their similarities and differences. Discuss the unity of form and function in these four types—that is, explain why each type would not perform as it does if its neurons were connected differently.
25. Contrast serial and parallel processing and describe how each can be involved in your everyday mental experiences.
26. State the essence of how immediate, short-term, and long-term memory work.
27. Explain how long-term potentiation and long-term depression influence what you remember and forget.

FIGURE 12.33 Alzheimer Disease. (a) Brain of a person who died of AD. Note the shrunken folds of cerebral tissue (gyri) and wide gaps (sulci) between them. (b) Cerebral tissue from a person with AD. The dense orange masses are senile plaques characteristic of AD.

a: Science Source; b: Jose Luis Calvo/Shutterstock

³²Alois Alzheimer (1864–1915), German neurologist

dietary antioxidants or antioxidant therapy can reduce the incidence or progression of AD.

Intense biomedical research efforts are currently geared toward identifying the causes of AD and developing treatment strategies. Three genes on chromosomes 1, 14, and 21 have been implicated in various forms of early- and late-onset AD. Interestingly, persons with Down syndrome (trisomy-21), who have three copies of chromosome 21 instead of the usual two, tend to show early-onset Alzheimer disease. Nongenetic (environmental) factors also seem to be involved.

As for treatment, considerable attention now focuses on trying to halt β -amyloid formation or stimulate the immune system to clear β -amyloid from the brain tissue.

Parkinson³³ disease (PD), also called *paralysis agitans* or *parkinsonism*, is a progressive loss of motor function typically beginning in a person's 50s or 60s. It is due to degeneration of dopamine-releasing neurons in a portion of the brainstem called the *substantia nigra* (**fig. 12.34**). A gene has recently been identified for a hereditary form of PD, but most cases are nonhereditary and of little-known cause; some authorities suspect environmental neurotoxins.

Dopamine (DA) is an inhibitory neurotransmitter that normally prevents excessive activity in motor centers of the brain called the *basal nuclei*. Degeneration of dopamine-releasing neurons leads to an excessive ratio of ACh to DA, causing hyperactivity of the basal nuclei. As a result, a person with PD suffers involuntary muscle contractions. These take such forms as shaking of the hands (tremor) and compulsive “pill-rolling” motions of the thumb and fingers. In addition, the

facial muscles may become rigid and produce a staring, expressionless face with a slightly open mouth. Patients experience a reduced range of motion. They take smaller steps and develop a slow, shuffling gait with a forward-bent posture and a tendency to fall forward. Speech becomes slurred and handwriting becomes cramped and eventually illegible. Tasks such as buttoning clothes and preparing food become increasingly laborious.

Patients cannot be expected to recover from PD, but its effects can be alleviated with drugs and physical therapy. Treatment with dopamine is ineffective because it can't cross the blood–brain barrier, but its precursor, levodopa (L-dopa), does cross the barrier and has been used to treat PD since the 1960s. L-dopa affords some relief, but it doesn't slow progression of the disease and it has undesirable side effects and is effective for only 5 to 10 years.

A surgical technique called *pallidotomy* has been used since the 1940s to quell severe tremors. It involves the destruction of a small portion of cerebral tissue in an area called the *globus pallidus*. Pallidotomy fell out of favor in the late 1960s when L-dopa came into common use. By the early 1990s, however, the limitations of L-dopa had become apparent, while MRI- and CT-guided methods had improved surgical precision and reduced the risks of brain surgery. Pallidotomy has thus made a comeback. Other surgical treatments for parkinsonism target other brain areas and involve either the destruction of tiny areas of tissue or the implantation of a stimulating electrode. Such procedures are generally used only in severe cases that are unresponsive to medication.

SYSTEM CONNECTIONS

Effects of the **NERVOUS SYSTEM** on Other Organ Systems

INTEGUMENTARY SYSTEM

Cutaneous nerves regulate piloerection, sweating, cutaneous vasoconstriction and vasodilation, and heat loss through the body surface, and provide for cutaneous sensations such as touch, itch, tickle, pressure, heat, and cold.

SKELETAL SYSTEM

Nervous stimulation maintains the muscle tension that stimulates bone growth and remodeling; nerves in the bones respond to strains and fractures.

MUSCULAR SYSTEM

Skeletal muscles cannot contract without nervous stimulation; the nervous system controls all body movements and muscle tone.

ENDOCRINE SYSTEM

The hypothalamus controls the pituitary gland; the sympathetic nervous system controls the adrenal medulla; neuroendocrine cells are neurons that secrete hormones such as oxytocin; sensory and other nervous input influences the secretion of numerous other hormones.

CIRCULATORY SYSTEM

The nervous system regulates the rate and force of the heartbeat, regulates blood vessel diameters, monitors and controls blood pressure and blood gas concentrations, routes blood to organs where needed, and influences blood clotting.

LYMPHOID AND IMMUNE SYSTEMS

Nerves to lymphatic organs influence the development and activity of immune cells; emotional states influence susceptibility to infection and other failures of immunity.

RESPIRATORY SYSTEM

The brainstem regulates the rhythm of breathing, monitors blood pH and blood gases, and adjusts the respiratory rate and depth to control these within normal ranges.

URINARY SYSTEM

Sympathetic nerves modify the rate of urine production by the kidneys; nervous stimulation of urinary sphincters aids in urine retention in the bladder, and nervous reflexes control its emptying.

DIGESTIVE SYSTEM

The nervous system regulates appetite, feeding behavior, digestive secretion and motility, and defecation.

REPRODUCTIVE SYSTEM

The nervous system regulates sex drive, arousal, and orgasm; the brain regulates the secretion of pituitary hormones that control spermatogenesis in males and the ovarian cycle in females; the nervous system controls various aspects of pregnancy and childbirth; the brain produces oxytocin, which is involved in labor contractions and lactation.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

12.1 Overview of the Nervous System

1. What the nervous and endocrine systems have in common
2. Three fundamental functions of the nervous system; the roles of receptors and effectors in carrying out these functions
3. Differences between the central nervous system (CNS) and peripheral nervous system (PNS); between the sensory and motor divisions of the PNS; and between the somatic and visceral subdivisions of both the sensory and motor divisions
4. The autonomic nervous system and its two divisions

12.2 Structure and Function of Neurons

1. Three fundamental physiological properties of neurons
2. Differences between sensory (afferent) neurons, interneurons (association neurons), and motor (efferent) neurons
3. The parts of a generalized multipolar neuron, and their functions
4. Differences between multipolar, bipolar, unipolar, and anaxonic neurons; an example of each
5. Ways in which neurons transport substances between the cell body and the distal ends of the axon

12.3 Supportive Cells

1. Six kinds of neuroglia; the structure and functions of each; and which kinds are found in the CNS and which ones in the PNS
2. Structure of the myelin sheath, and how CNS and PNS glial cells produce it
3. How axon diameter and the presence or absence of myelin affect the conduction speed of the axon
4. The regeneration of a damaged nerve; the roles of Schwann cells, the basal lamina, and neurolemma in regeneration; and why CNS neurons cannot regenerate

12.4 Electrophysiology of Neurons

1. The meanings of *electrical potential* and *resting membrane potential* (RMP); the typical voltage of an RMP

2. What an electrical current is, and how sodium ions and gated membrane channels generate a current
3. How stimulation of a neuron generates a local potential; the physiological properties of a local potential
4. Special properties of the trigger zone and unmyelinated regions of an axon that enable these regions to generate action potentials
5. The mechanism of an action potential; how it relates to ion flows and the action of membrane channels; and what is meant by *depolarization* and *repolarization* of the plasma membrane during local and action potentials
6. The all-or-none law and how it applies to an action potential; other properties of action potentials in contrast to local potentials
7. The basis and significance of the refractory period that follows an action potential
8. How one action potential triggers another; how the continuous conduction seen in unmyelinated axons result from a chain reaction of action potentials; and what normally prevents the signal from traveling backward to the cell body
9. Saltatory conduction in a myelinated axon; differences in conduction mechanisms of the myelin sheath gaps and internodal segments; and why signals travel faster in myelinated axons than in unmyelinated axons of comparable size

12.5 Synapses

1. The structure and locations of synapses
2. The role of neurotransmitters in synaptic transmission
3. Categories of neurotransmitters and common examples of each
4. Why the same neurotransmitter can have different effects on different cells
5. Excitatory synapses; how acetylcholine and norepinephrine excite a postsynaptic neuron
6. Inhibitory synapses; how γ -aminobutyric acid (GABA) inhibits a postsynaptic neuron
7. How second-messenger systems function at synapses
8. Three ways in which synaptic transmission is ended
9. Neuromodulators, their chemical nature, and how they affect synaptic transmission

12.6 Neural Integration

1. Why synapses slow down nervous communication; the overriding benefit of synapses
2. The meaning of *excitatory* and *inhibitory postsynaptic potentials* (EPSPs and IPSPs)
3. Why the production of an EPSP or IPSP may depend on both the neurotransmitter released by the presynaptic neuron and the type of receptor on the postsynaptic neuron
4. How a postsynaptic neuron's decision to fire depends on the ratio of EPSPs to IPSPs
5. Temporal and spatial summation, where they occur, and how they determine whether a neuron fires
6. Mechanisms of presynaptic facilitation and inhibition, and how communication between two neurons can be strengthened or weakened by a third neuron employing one of these mechanisms
7. Mechanisms of neural coding; how a neuron communicates qualitative and quantitative information
8. Why the refractory period sets a limit to how frequently a neuron can fire
9. The meanings of *neural pool* and *neural circuit*
10. The difference between a neuron's discharge zone and facilitated zone, and how this relates to neurons working in groups
11. Diverging, converging, reverberating, and parallel after-discharge circuits of neurons; examples of their relevance to familiar body functions
12. The difference between serial and parallel processing of information and how they influence everyday body functions
13. The cellular basis of memory; what memory consists of in terms of neural pathways, and how it relates to synaptic plasticity and potentiation
14. Types of things remembered in immediate memory, short-term memory (STM), and long-term memory (LTM), and in the explicit and implicit forms of LTM
15. Neural mechanisms thought to be involved in these different forms of memory and in forgetting

STUDY GUIDE

► Testing Your Recall

Answers in Appendix A

- The integrative functions of the nervous system are performed mainly by
 - afferent neurons.
 - efferent neurons.
 - neuroglia.
 - sensory neurons.
 - interneurons.
- The highest density of voltage-gated ion channels is found in the _____ of a neuron.
 - dendrites
 - cell body
 - myelin sheath gaps
 - internodal segments
 - axon terminals
- The cell body of a mature neuron lacks
 - a nucleus.
 - endoplasmic reticulum.
 - lipofuscin.
 - centrioles.
 - ribosomes.
- The glial cells that fight infections in the CNS are
 - microglia.
 - satellite cells.
 - ependymal cells.
 - oligodendrocytes.
 - astrocytes.
- Posttetanic potentiation of a synapse increases the amount of _____ in the axon terminal.
 - neurotransmitter
 - neurotransmitter receptors
 - calcium
 - sodium
 - NMDA
- An IPSP is _____ of the postsynaptic neuron.
 - a refractory period
 - an action potential

- Neurons that convey information to the CNS are called sensory, or _____, neurons.
- To perform their role, neurons must have the properties of excitability, secretion, and _____.
- The _____ is a period of time in which a neuron is producing an action potential and cannot respond to another stimulus of any strength.
- Neurons receive incoming signals by way of specialized extensions of the cell called _____.
- In the CNS, myelin is produced by glial cells called _____.
- A myelinated axon can produce action potentials only in specialized regions called _____.
- The trigger zone of a neuron consists of its _____ and _____.
- The neurotransmitter secreted at an adrenergic synapse is _____.
- A presynaptic neuron cannot cause other neurons in its _____ to fire, but it can make them more sensitive to stimulation from other presynaptic neurons.
- _____ are substances released along with a neurotransmitter that modify the neurotransmitter's effect.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|------------|------------|-------------|
| 1. antero- | 3. astro- | 7. -grad |
| 2. -aps | 4. dendro- | 8. neuro- |
| | 5. -fer | 9. sclero- |
| | 6. gangli- | 10. somato- |

STUDY GUIDE

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. A neuron may have anywhere from one to several axons.
2. Astrocytes perform the same function in the brain as Schwann cells do in the peripheral nerves.
3. A resting neuron has a higher concentration of Na^+ in its cytoplasm than in the extracellular fluid surrounding it.
4. During an action potential, most of the Na^+ and K^+ exchange places across the plasma membrane.
5. Excitatory postsynaptic potentials lower the threshold of a neuron and thus make it easier to stimulate.
6. In theory, there is no upper limit to how often a neuron can fire if it is stimulated strongly enough.
7. A given neurotransmitter has the same effect no matter where in the body it is secreted.
8. Myelinated axons conduct signals more rapidly than unmyelinated ones because they have gaps in the myelin sheath.
9. Learning occurs by increasing the number of neurons in the brain tissue.
10. Dead neurons in the brain are quickly replaced by mitosis of surviving neurons.

► Testing Your Comprehension

1. Schizophrenia is sometimes treated with drugs such as chlorpromazine that inhibit dopamine receptors. A side effect is that patients begin to develop muscle tremors, speech impairment, and other disorders similar to Parkinson disease. Explain.
2. Hyperkalemia is an excess of potassium in the extracellular fluid. What effect would this have on the resting membrane potentials of the nervous system and on neural excitability?
3. Suppose a poison were to slow down the Na^+-K^+ pumps of nerve cells. How would this affect the resting membrane potentials of neurons? Would it make neurons more excitable than normal, or make them more difficult to stimulate? Explain.
4. The unity of form and function is an important concept in understanding synapses. Give two structural reasons why nerve signals cannot travel backward across a chemical synapse. What could be the consequences if signals did travel freely in both directions?
5. Positive feedback is usually harmful to the body, or even life-threatening, but there are a few cases where it is beneficial and necessary. Identify such a case in neuron electrophysiology. If necessary, review the defining characteristics of positive feedback in section 1.6d.

BRUSHING UP

- This chapter assumes that you have a basic knowledge of neuron structure (see section 12.2c).
- Spinal cord anatomy is described here in terms that assume you are familiar with anatomy of the spinal (vertebral) column in section 8.3.
- To understand spinal reflexes, you must be familiar with the ways muscles work together at a joint, especially antagonistic muscles (see fig. 10.4 and the associated discussion).
- Understanding spinal reflexes also requires a knowledge of excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) and the parallel after-discharge type of neural circuit (see sections 12.6a, 12.6d).

Every year in the United States, thousands of people suffer paralyzing spinal cord injuries, often with devastating effects on their quality of life. The treatment of such injuries is one of the most lively areas of medical research today. Therapists in this specialty must know spinal cord anatomy and function to understand their patients' functional deficits and prospects for improvement and to plan a regimen of treatment. Such knowledge is necessary, as well, for understanding paralysis resulting from strokes and other brain injuries. The spinal cord is the "information highway" that connects the brain with the lower body; it contains the neural routes that explain why a lesion to a specific part of the brain results in a functional loss in a specific locality in the lower body.

In this chapter, we will study not only the spinal cord but also the spinal nerves that arise from it with ladderlike regularity at intervals along its length. Thus, we will examine components of both the central and peripheral nervous systems, but these are so closely related, structurally and functionally, that it is appropriate to consider them together. Similarly, the brain and cranial nerves will be considered together in the following chapter. Chapters 13 and 14 therefore elevate our study of the nervous system from the cellular level (chapter 12) to the organ and system levels.

13.1 The Spinal Cord

Expected Learning Outcomes

When you have completed this section, you should be able to

- state the three principal functions of the spinal cord;
- describe its gross and microscopic structure; and
- trace the pathways followed by nerve signals traveling up and down the spinal cord.

13.1a Functions

The spinal cord serves four principal functions:

1. **Conduction.** It contains bundles of nerve fibers that conduct information up and down the cord, connecting different levels of the trunk with each other and with the brain. This enables sensory information to reach the brain, motor commands to reach the effectors, and input received at one level of the cord to affect output from another level.
2. **Neural integration.** Pools of spinal neurons receive input from multiple sources, integrate the information, and execute an appropriate output. For example, the spinal cord can integrate the stretch sensation from a full bladder with cerebral input concerning the appropriate time and place to urinate and execute control of the bladder accordingly.
3. **Locomotion.** Walking involves repetitive, coordinated contractions of several muscle groups in the limbs. Motor neurons in the brain initiate walking and determine its speed, distance, and direction, but the simple repetitive muscle contractions that put one foot in front of another, over and over, are coordinated by groups of neurons called **central pattern generators** in the cord. These neural circuits produce the sequence of outputs to the extensor and flexor muscles that cause alternating movements of the lower limbs.
4. **Reflexes.** Spinal reflexes play vital roles in posture, motor coordination, and protective responses to pain or injury.

13.1b Surface Anatomy

The **spinal cord** (fig. 13.1) arises from the brainstem at the foramen magnum of the skull. It passes through the vertebral canal as far as the inferior margin of the first lumbar vertebra (L1) or slightly beyond. In adults, it averages about 45 cm long and 1.8 cm thick (about as thick as one's little finger). Early in fetal development, the cord extends for the full length of the vertebral column. However, the vertebral column grows faster than the spinal cord, so the cord extends only to L3 by the time of birth and to L1 in an adult. Thus, it occupies only the upper two-thirds of the vertebral canal; the lower one-third is described shortly.

The cord gives rise to 31 pairs of *spinal nerves*. Although the spinal cord isn't visibly segmented, the part supplied by each pair of nerves is called a **segment**. The cord exhibits longitudinal grooves on its anterior and posterior sides—the *anterior median fissure* and *posterior median sulcus*, respectively (fig. 13.2).

The spinal cord is divided into **cervical**, **thoracic**, **lumbar**, and **sacral regions**. It may seem odd that it has a sacral region when the cord itself ends well above the sacrum. These regions, however, are named for the level of the vertebral column from which the spinal nerves emerge, not for the vertebrae that contain the cord itself.

In two areas, the cord is a little thicker than elsewhere. In the inferior cervical region, a **cervical enlargement** gives rise to nerves of the upper limbs. In the lumbosacral region, there is a similar **lumbosacral enlargement** that issues nerves to the pelvic

**FIGURE 13.1** The Spinal Cord, Posterior View.

(a) Overview of spinal cord structure. (b) Detail of the spinal cord and associated structures. **APR**

region and lower limbs. Inferior to the lumbosacral enlargement, the cord tapers to a point called the **medullary cone**. Arising from the lumbosacral enlargement and medullary cone is a bundle of nerve roots that occupy the vertebral canal from L2 to S5. This bundle, named the **cauda equina**¹ (CAW-duh ee-KWY-nah) for its resemblance to a horse's tail, innervates the pelvic organs and lower limbs.

▶▶▶ APPLY WHAT YOU KNOW

Spinal cord injuries commonly result from fractures of vertebrae C5 to C6, but never from fractures of L3 to L5. Explain both observations.

¹cauda = tail; equin = horse

13.1c Meninges of the Spinal Cord

The spinal cord and brain are enclosed in three fibrous membranes called **meninges**² (meh-NIN-jeez)—singular, *meninx* (MEN-inks) (fig. 13.2). These membranes separate the soft tissue of the central nervous system from the bones of the vertebrae and skull. From superficial to deep, they are the dura mater, arachnoid mater, and pia mater.

The **dura mater**³ (DOO-ruh MAH-tur) forms a loose-fitting sleeve called the **dural sheath** around the spinal cord. It is a tough membrane about as thick as a rubber kitchen glove, composed of multiple layers of dense irregular connective tissue. The space between the sheath and vertebral bones, called the **epidural space**, is occupied by

²menin = membrane

³dura = tough; mater = mother, womb

FIGURE 13.2 Cross-Sectional Anatomy of the Cervical Spinal Cord. (a) Superior view showing relationships of vertebra C5 with the spinal cord, spinal nerves, and meninges. (b) Anterior view of three segments of the spinal cord, meninges, and spinal nerves. See figure 13.3 for details of the gray and white matter.

blood vessels, adipose tissue, and loose connective tissue. Anesthetics can be introduced to this space to block pain signals during childbirth or surgery; this procedure is called *epidural anesthesia*.

The **arachnoid⁴ mater** (ah-RACK-noyd) consists of the *arachnoid membrane*—five or six layers of squamous to cuboidal

⁴*arachn* = spider, spider web; *oid* = resembling

cells adhering to the inside of the dura—and a looser array of cells and collagenous and elastic fibers spanning the gap between the arachnoid membrane and the pia mater. This gap, the **subarachnoid space**, is filled with **cerebrospinal fluid (CSF)** (described in chapter 14). Inferior to the medullary cone, the subarachnoid space is called the **lumbar cistern** and is occupied by the cauda equina and CSF. When a sample of CSF is needed for clinical purposes, it

FIGURE 13.3 Cross Section of the Spinal Cord (Lumbar Region). Nervous tissue is often histologically stained with silver compounds, which give the gray matter a brown or golden color and give white matter a lighter tan to amber color, as seen here and on many slides the student may encounter.

Ed Reschke/Stone/Getty Images

is taken from the lumbar cistern by a procedure called a **spinal tap** or **lumbar puncture** (see Deeper Insight 13.1).

The **pia⁵ mater** (PEE-uh) is a delicate, transparent membrane composed of one or two layers of squamous to cuboidal cells and delicate collagenous and elastic fibers. It closely follows the contours of the spinal cord. It continues beyond the medullary cone as a fibrous strand, the **terminal filum**, within the lumbar cistern. At the level of vertebra S2, it exits the lower end of the cistern and fuses with the dura mater, and the two form a **coccygeal ligament** that anchors the cord and meninges to vertebra Co1. At regular intervals along the cord, extensions of the pia called **denticulate⁶ ligaments** extend through the arachnoid to the dura, anchoring the cord and limiting side-to-side movements.

13.1d Cross-Sectional Anatomy

Figure 13.2a shows the relationship of the spinal cord to a vertebra and spinal nerve, and **figure 13.3** shows the cord itself in more detail. The spinal cord, like the brain, consists of two kinds of nervous tissue called gray and white matter. **Gray matter** has a relatively dull color because it contains little myelin. It contains the cell bodies, dendrites, and proximal parts of the axons of neurons. It is the site of synaptic contact between neurons, and therefore the site of all neural integration in the spinal cord. **White matter**, by contrast, has a bright, pearly white appearance due to an abundance of myelin. It is composed of axon bundles that course up and down the spinal cord, providing avenues of communication between different levels of the CNS.

This chapter will refer to axons traveling through nerves and CNS white matter by their customary synonym, **nerve fibers**. Be careful not to confuse this expression with the muscle and connective tissue fibers discussed later in this chapter.

Gray Matter

The spinal cord has a central core of gray matter that looks somewhat butterfly- or H-shaped in cross sections. The core consists mainly of

two **posterior (dorsal) horns**, which extend toward the posterolateral surfaces of the cord, and two thicker **anterior (ventral) horns**, which extend toward the anterolateral surfaces. The right and left sides of the gray matter are connected by a median bridge called the **gray commissure**. In the middle of the commissure is the **central canal**, which is collapsed in most areas of the adult spinal cord, but in some places (and in young children) remains open, lined with ependymal cells, and filled with CSF.

The posterior horn receives sensory nerve fibers from the spinal nerves, which usually synapse with networks of interneurons in the horn. The anterior horn contains the large cell bodies of motor neurons whose axons lead out to the skeletal muscles. The interneurons and motor neurons are especially abundant in the cervical and lumbosacral enlargements and are quite conspicuous in histological sections from these levels. The high density of neurons in these regions is related to motor control and sensation in the upper and lower limbs.

An additional **lateral horn** is visible on each side of the gray matter from segments T2 through L1 of the cord. It contains neurons of the sympathetic nervous system, which send their axons out of the cord by way of the anterior root along with the somatic efferent fibers.

White Matter

The white matter of the spinal cord surrounds the gray matter. Its nerve fibers (axons) travel in three large bundles called the **posterior, lateral, and anterior funiculus⁷** (few-NIC-you-lus) on each side of the cord. Each funiculus is subdivided into smaller fiber compartments called **spinal tracts**, or **fasciculi⁸** (fah-SIC-you-lie), discussed next.

13.1e Spinal Tracts

Knowledge of the locations and functions of the spinal tracts is essential in diagnosing and managing spinal cord injuries. **Ascending tracts** carry sensory information up the

⁵*pia* = through mistranslation, now construed as tender, thin, or soft

⁸*fascicul* = little bundle

DEEPER INSIGHT 13.1

CLINICAL APPLICATION

Spinal Tap

Several neurological diseases are diagnosed in part by examining cerebrospinal fluid (CSF) for bacteria, fungi, blood, white blood cells, or abnormalities of chemical composition. CSF is obtained by a procedure called a **spinal tap** or **lumbar puncture**. The patient leans forward or lies on one side with the spine flexed, thus spreading the vertebral laminae and spinous processes apart (**fig. 13.4**). The skin over the lumbar vertebrae is anesthetized, and a needle is inserted between the spinous processes of L3 and L4 (sometimes L4 and L5). This is the safest place to obtain CSF because the spinal cord doesn't extend this far and

isn't exposed to injury by the needle. At a depth of 4 to 6 cm, the needle punctures the dura mater and enters the lumbar cistern. CSF normally drips out at a rate of about 1 drop per second. A lumbar puncture is not performed if a patient has signs of high intracranial pressure, because the sudden release of pressure (causing CSF to jet from the puncture) can cause fatal herniation of the brainstem and cerebellum into the vertebral canal. CSF sampling is often used in the diagnosis of meningitis, brain bleeds, syphilis, multiple sclerosis, Guillain-Barré syndrome, and other infectious, inflammatory, and metabolic diseases.

FIGURE 13.4 Spinal Tap (Lumbar Puncture).

cord, and **descending tracts** conduct motor signals down (**fig. 13.5**). All nerve fibers in a given tract have a similar origin, destination, and function. Many of these fibers have their origin or destination in a region called the *brainstem*. Described more fully in chapter 14, this is a vertical stalk that supports the

large *cerebellum* at the rear of the head and, even larger, two *cerebral hemispheres* that dominate the brain. In the following discussion, you will find references to brainstem and other regions where spinal tracts begin and end. Spinal cord anatomy will mean more as you study the brain.

FIGURE 13.5 Tracts of the Spinal Cord. All of the illustrated tracts occur on both sides of the cord, but only the ascending sensory tracts are shown on the left (red), and only the descending motor tracts on the right (green).

? If you were told that this cross section is either at level C5 or T10, how could you determine which is correct?

Several of these tracts undergo **decussation**⁹ (DEE-cuh-SAY-shun) as they pass up or down the brainstem and spinal cord—meaning that they cross over from the left side of the body to the right, or vice versa. As a result, the left side of the brain receives sensory information from the right side of the body and sends motor commands to that side, while the right side of the brain senses and controls the left side of the body. Therefore, a stroke that damages motor centers of the right side of the brain can cause paralysis of the left limbs and vice versa.

When the origin and destination of a tract are on opposite sides of the body, we say they are **contralateral**¹⁰ to each other. When a tract doesn't decussate, its origin and destination are on the same side of the body and we say they are **ipsilateral**.¹¹

The major spinal tracts are summarized in **table 13.1** and the following text. Bear in mind that each tract is repeated on the right and left sides of the spinal cord.

Ascending Tracts

Ascending tracts carry sensory signals up the spinal cord. Sensory signals typically travel across three neurons from their origin in the receptors to their destination in the brain: a **first-order neuron** that detects a stimulus and conducts a signal to the spinal cord or brainstem; a **second-order neuron** that continues as far as a “gateway” called the *thalamus* at the upper end of the brainstem; and a **third-order neuron** that carries the signal the rest of the way to the cerebral cortex. The axons of these neurons are called the *first-through third-order nerve fibers* (**fig. 13.6**).

The major ascending tracts are as follows. The names of most of them consist of the prefix *spino-* followed by a root denoting the destination of its fibers in the brain, although this naming system does not apply to the first two.

- The posterior funiculus consists of the **cuneate**¹² **fasciculus** (CUE-nee-ate) and **gracile**¹³ **fasciculus** (GRAS-el) from level T6 to the brain, and only the gracile fasciculus from T7 down (**fig. 13.6a**). The gracile fasciculus carries sensory signals from the lower trunk and lower limbs, and the cuneate fasciculus from the chest and upper limbs. These signals include the senses of vibration, visceral pain, deep touch, and especially proprioception from the lower limbs and lower trunk. **Proprioception**¹⁴ is one's nonvisual sense of the position and movements of the body and its parts, coming from sensory nerve endings in the muscles, tendons, and joints. The brain uses this information to adjust muscle tone and actions to maintain equilibrium (balance), posture, and coordination. The first-order nerve fibers of these fasciculi end in the medulla oblongata of the brainstem, but the second-order fibers decussate there to the other side of the brain. Thus, the right brain receives signals from the left side of the body and vice versa.
- The **spinothalamic tract** (SPY-no-tha-LAM-ic) (**fig. 13.6b**) and some smaller tracts form the *anterolateral system*, which passes up the anterior and lateral funiculi of the spinal cord. The spinothalamic tract carries signals for pain, temperature, pressure, tickle, itch, and light touch. Light touch is the

⁹*decuss* = to cross, form an X

TABLE 13.1 Major Spinal Cord Tracts			
Tract	Funiculus	Decussation	Functions
Ascending (Sensory) Tracts			
Gracile fasciculus	Posterior	In medulla	Sensations of limb and trunk position and movement, deep touch, visceral pain, and vibration, below level T6
Cuneate fasciculus	Posterior	In medulla	Same as gracile fasciculus, from level T6 up
Spinothalamic	Lateral and anterior	In spinal cord	Sensations of light touch, tickle, itch, temperature, pain, and pressure
Spinoreticular	Lateral and anterior	In spinal cord (some fibers)	Sensation of pain from tissue injury
Posterior spinocerebellar	Lateral	None	Feedback from muscles (proprioception)
Anterior spinocerebellar	Lateral	In spinal cord	Same as posterior spinocerebellar
Descending (Motor) Tracts			
Lateral corticospinal	Lateral	In medulla	Fine control of limbs
Anterior corticospinal	Anterior	In spinal cord	Fine control of limbs
Tectospinal	Anterior	In midbrain	Reflexive head turning in response to visual and auditory stimuli
Lateral reticulospinal	Lateral	None	Balance and posture; regulation of awareness of pain
Medial reticulospinal	Anterior	None	Same as lateral reticulospinal
Lateral vestibulospinal	Anterior	None	Balance and posture
Medial vestibulospinal	Anterior	In medulla (some fibers)	Control of head position

sensation produced, for example, by stroking hairless skin with a feather or cotton wisp, without indenting the skin. In this pathway, first-order neurons end in the posterior horn of the spinal cord near the point of entry. Here they synapse with second-order neurons, which decussate and form the contralateral ascending spinothalamic tract. These fibers lead all the way to the thalamus. Therefore, here again, each hemisphere of the brain receives sensory input from the opposite side of the body.

- The **spinoreticular tract** carries pain signals up the anterolateral system. First-order pain fibers enter the posterior horn and immediately synapse with second-order neurons. These decussate to the opposite anterolateral system, ascend the cord, and end in a loosely organized core of gray matter called the *reticular*¹⁵ formation in the medulla oblongata and pons. Pain pathways are further discussed in chapter 16.
- The **posterior and anterior spinocerebellar tracts** (SPY-no-SERR-eh-BEL-ur) travel through the lateral funiculus and carry proprioceptive signals from the limbs and trunk to the cerebellum at the rear of the brain. Their first-order neurons originate in muscles and tendons and end in the posterior horn of the spinal cord. Second-order neurons send their fibers up the spinocerebellar tracts and end in the cerebellum. Both tracts provide the cerebellum with feedback needed to coordinate muscle action.

Descending Tracts

Descending tracts carry motor signals down the brainstem and spinal cord. A descending motor pathway typically involves two neurons called the upper and lower motor neurons. The **upper motor neuron** begins with a cell body in the cerebral cortex or brainstem and has an axon that terminates on a **lower motor neuron** in the brainstem or spinal cord. The axon of the lower motor neuron then leads the rest of the way to the muscle or other target organ. The names of most descending tracts consist of a word root denoting the point of origin in the brain, followed by the suffix *-spinal*. The major descending tracts are described here.

- The **lateral and anterior corticospinal tracts** (COR-tih-co-SPY-nul) (**fig. 13.7**) carry motor signals from the cerebral cortex for precise, finely coordinated limb movements. The fibers (axons) of this system form ridges called *pyramids* on the anterior surface of the medulla oblongata, so these tracts were once called *pyramidal tracts*. Their fibers decussate either in the lower medulla or lower in the spinal cord, so each cerebral hemisphere controls muscles on the contralateral side of the body. The anterior tract gets smaller as it descends and gives off nerve fibers, and usually disappears by the midthoracic level.
- The **tectospinal**¹⁶ tract (TEC-toe-SPY-nul) begins in the roof of the midbrain and descends the contralateral spinal

¹⁵*reticul* = little network

¹⁶*tectum* = roof (of the midbrain)

FIGURE 13.6 Some Ascending Pathways of the CNS. The spinal cord, medulla, and midbrain are shown in cross section and the cerebrum and thalamus (top) in frontal section. Nerve signals enter the spinal cord at the bottom of the figure and carry somatosensory information up to the cerebral cortex. (a) The cuneate fasciculus. (b) The spinothalamic tract.

cord only as far as the neck. It is involved in reflex turning of the head, especially in response to sights and sounds.

- The **lateral and medial reticulospinal tracts** (reh-TIC-you-lo-SPY-nul) originate in the reticular formation of the brainstem. They control muscles of the upper and lower

limbs, especially to maintain posture and balance. They also contain *descending analgesic pathways* that regulate the transmission of pain signals to the brain.

- The **lateral and medial vestibulospinal tracts** (vess-TIB-you-lo-SPY-nul) begin in the brainstem *vestibular nuclei*,

FIGURE 13.7 Two Descending Pathways of the CNS. The lateral and anterior corticospinal tracts, which carry signals for voluntary muscle contraction. Nerve signals originate in the cerebral cortex at the top of the figure and carry motor commands down the spinal cord.

which receive signals for balance from the inner ear. The lateral vestibulospinal tract passes down the anterior funiculus and facilitates neurons that control extensor muscles of the limbs, thus inducing the limbs to stiffen and straighten. This is an important reflex in responding to body tilt and keeping one's balance. The medial vestibulospinal tract descends through the anterior funiculus on both sides of the cord and ends in the neck. It plays a role in the control of head position.

▶▶▶ APPLY WHAT YOU KNOW

You are blindfolded and either a tennis ball or an iron ball is placed in your right hand. What spinal tract(s) would carry the signals that enable you to discriminate between these two objects?

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. Name the four major regions and two enlargements of the spinal cord.
2. Describe the distal (inferior) end of the spinal cord and the contents of the vertebral canal from level L2 to S5.
3. Sketch a cross section of the spinal cord showing the anterior and posterior horns. Where are the gray and white matter? Where are the funiculi and tracts?
4. Give an anatomical explanation of why a stroke in the right cerebral hemisphere can paralyze the limbs on the left side of the body.
5. Identify each of the following spinal tracts—the gracile fasciculus and the lateral corticospinal, lateral reticulospinal, and spinothalamic tracts—with respect to whether it is ascending or descending; its origin and destination; and what sensory or motor purposes it serves.

13.2 The Spinal Nerves

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. describe the anatomy of nerves and ganglia in general;
- b. describe the attachments of a spinal nerve to the spinal cord;
- c. trace the branches of a spinal nerve distal to its attachments;
- d. name the five plexuses of spinal nerves and describe their general anatomy;
- e. name some major nerves that arise from each plexus and identify what they innervate; and
- f. explain the relationship of dermatomes to the spinal nerves.

DEEPER INSIGHT 13.2

CLINICAL APPLICATION

Poliomyelitis and Amyotrophic Lateral Sclerosis

*Poliomyelitis*¹⁷ and *amyotrophic lateral sclerosis*¹⁸ (ALS) are two diseases that involve destruction of motor neurons. In both diseases, the skeletal muscles atrophy from lack of innervation.

Poliomyelitis is caused by the poliovirus, which destroys motor neurons in the brainstem and anterior horn of the spinal cord. Signs of polio include muscle pain, weakness, and loss of some reflexes, followed by paralysis, muscular atrophy, and sometimes respiratory arrest. The virus spreads by fecal contamination of water. Historically, polio afflicted many children who contracted the virus from contaminated public swimming pools. For a time, the polio vaccine nearly eliminated new cases, but the disease has lately begun to reemerge among children in some parts of the world because of antivaccination politics.

ALS is also known as Lou Gehrig¹⁹ disease after the baseball player who had to retire from the sport because of it. It is marked not only by the degeneration of motor neurons and atrophy of the muscles, but also sclerosis (scarring) of the lateral regions of the spinal cord—hence its name. Most cases occur when astrocytes fail to reabsorb the neurotransmitter glutamate from the tissue fluid, allowing it to accumulate to a neurotoxic level. The early signs of ALS include muscular weakness and difficulty in speaking, swallowing, and using the hands. Sensory and intellectual functions remain unaffected, as evidenced by the accomplishments of astrophysicist and best-selling author Stephen Hawking (fig. 13.8), who was stricken with ALS in college. Despite near-total paralysis, he had a slowly progressing form of the disease, remained intellectually undiminished, and communicated with the aid of a speech synthesizer and computer. Tragically, many people are quick to assume that those who have lost most of their ability to communicate their ideas and feelings have few ideas and feelings to communicate. To a victim, this may be more unbearable than the loss of motor function itself.

FIGURE 13.8 Stephen Hawking (1942–2018). “When I was first diagnosed with ALS, I was given two years to live. Now 45 years later, I am doing pretty well” (CNN interview, 2010).

13.2a General Anatomy of Nerves and Ganglia

The spinal cord communicates with the rest of the body by way of the spinal nerves. Before we discuss those specific nerves, however, it is necessary to be familiar with the structure of nerves and ganglia in general.

A **nerve** is a cordlike organ composed of numerous nerve fibers (axons) bound together by connective tissue (fig. 13.9). If we compare a *nerve fiber* to a wire carrying an electrical current in one direction, a *nerve* would be comparable to an electrical cable composed of hundreds of wires carrying currents in opposite directions. A nerve contains anywhere from a few nerve fibers to a million (as in the optic nerve). Nerves usually have a pearly white color and resemble frayed string as they divide into smaller and smaller branches. As we move away from the spinal nerves proper, the smaller branches are called **peripheral nerves**, and their disorders are collectively called *peripheral neuropathy*.

Nerve fibers of the peripheral nervous system are wrapped in Schwann cells, which form a neurolemma and often a myelin sheath around the fiber (see section 12.3b). External to the neurolemma, each fiber is surrounded by a basal lamina and then a thin sleeve of loose connective tissue called the **endoneurium**. In most nerves, the fibers are gathered in bundles called **fascicles**, each wrapped in a sheath called the **perineurium**. The nerve fibers within any one fascicle are similar in origin and destination. The perineurium is composed of up to 20 layers of overlapping, squamous, epithelium-like cells surrounded by collagen fibers. Several fascicles are then bundled together and wrapped in an outer **epineurium** to compose the nerve as a whole. The epineurium consists of dense irregular connective tissue and protects the nerve from stretching and injury. Nerves have a high metabolic rate and need a plentiful blood supply, which is furnished by blood vessels that penetrate these connective tissue coverings.

▶▶▶ APPLY WHAT YOU KNOW

How does the structure of a nerve compare to that of a skeletal muscle? Which of the descriptive terms for nerves have similar counterparts in muscle histology?

¹⁷polio = gray matter; myel = spinal cord; itis = inflammation

¹⁸a = without; myo = muscle; troph = nourishment; sclerosis = hardening

¹⁹Lou Gehrig (1903–41), American baseball player

FIGURE 13.9 Anatomy of a Nerve. (a) A spinal nerve and its association with the spinal cord. (b) Cross section of a nerve. Individual nerve fibers show as tiny dots, each surrounded by a light ring of myelin.

b: PASIEKA/Science Photo Library/Getty Images

As we saw in chapter 12, peripheral nerve fibers are of two kinds: sensory (afferent) fibers carrying signals from sensory receptors to the CNS, and motor (efferent) fibers carrying signals from the CNS to muscles and glands. Both types can be classified as *somatic* or *visceral* and as *general* or *special* depending on the organs they innervate (**table 13.2**).

Purely **sensory nerves**, composed only of afferent fibers, are rare; they include nerves for smell and vision. **Motor nerves** carry only efferent fibers. Most nerves, however, are **mixed nerves**, which consist of both afferent and efferent fibers and therefore conduct signals in two directions. However, any one fiber in the nerve conducts signals

in one direction only. Many nerves commonly described as motor are actually mixed because they carry sensory signals of proprioception (body position and movements) from the muscle back to the CNS.

If a nerve resembles a string, a **ganglion**²⁰ resembles a knot in the string. A ganglion is a cluster of nerve cell bodies outside the CNS. It is enveloped in an epineurium continuous with that of the nerve. Among the cell bodies are bundles of nerve fibers leading into and out of the ganglion. **Figure 13.10** shows a type of ganglion associated with the spinal nerves.

²⁰ *gangli* = knot

TABLE 13.2 The Classification of Nerve Fibers	
Class	Description
Afferent fibers	Carry sensory signals from receptors to the CNS
Efferent fibers	Carry motor signals from the CNS to effectors
Somatic fibers	Innervate skin, skeletal muscles, bones, and joints
Visceral fibers	Innervate blood vessels, glands, and viscera
General fibers	Innervate widespread organs such as muscles, skin, glands, viscera, and blood vessels
Special fibers	Innervate more localized organs in the head, including the eyes, ears, olfactory and taste receptors, and muscles of chewing, swallowing, and facial expression

13.2b Spinal Nerves

There are 31 pairs of **spinal nerves**: 8 cervical (C1–C8), 12 thoracic (T1–T12), 5 lumbar (L1–L5), 5 sacral (S1–S5), and 1 coccygeal (Co1) (fig. 13.11). The first cervical nerve emerges between

the skull and atlas, and the others emerge through intervertebral foramina, including the anterior and posterior foramina of the sacrum and the sacral hiatus. Thus, spinal nerves C1 through C7 emerge superior to the correspondingly numbered vertebrae (nerve C5 above vertebra C5, for example); nerve C8 emerges inferior to vertebra C7; and below this, all the remaining nerves emerge inferior to the correspondingly numbered vertebrae (nerve L3 inferior to vertebra L3, for example).

Proximal Branches

Each spinal nerve arises from two points of attachment to the spinal cord. In each segment of the cord, six to eight nerve **rootlets** emerge from the anterior surface and converge to form the **anterior (ventral) root** of the spinal nerve. Another six to eight rootlets emerge from the posterior surface and converge to form the **posterior (dorsal) root** (figs. 13.12, 13.13). A short distance away from the spinal cord, the posterior root swells into a **posterior (dorsal) root ganglion**, which contains the cell bodies of sensory neurons (fig. 13.10). There is no corresponding ganglion on the anterior root because the cell bodies are in the anterior horns of the spinal cord.

FIGURE 13.10 Anatomy of a Ganglion (Longitudinal Section). The posterior root ganglion contains the cell bodies of unipolar sensory neurons conducting signals from peripheral sense organs toward the spinal cord. Below this is the anterior root of the spinal nerve, which conducts motor signals away from the spinal cord, toward peripheral effectors. (The anterior root is not part of the ganglion.)

? Where are the cell bodies of the neurons that give rise to the motor nerve fibers seen here?

FIGURE 13.11 The Spinal Nerve Roots and Plexuses, Posterior View.

Slightly distal to the posterior root ganglion, the anterior and posterior roots merge, leave the dural sheath, and form the spinal nerve proper (fig. 13.12). The nerve then exits the vertebral canal through the intervertebral foramen. The spinal nerve is a mixed nerve, carrying sensory signals to the spinal cord by way of the posterior root and ganglion, and motor signals out to more distant parts of the body by way of the anterior root.

The anterior and posterior roots are shortest in the cervical region and become longer inferiorly. The roots that arise from segments L2 to Co1 of the cord form the cauda equina. Some viruses invade the CNS by way of the spinal nerve roots (see Deeper Insight 13.3).

Distal Branches

Distal to the vertebrae, the branches of a spinal nerve are more complex (fig. 13.14). Immediately after emerging from the intervertebral foramen, the nerve divides into an **anterior ramus**²¹

(RAY-mus), **posterior ramus**, and a small **meningeal branch**. Thus, each spinal nerve branches on both ends—into anterior and posterior *roots* approaching the spinal cord, and anterior and posterior *rami* leading away from the vertebral column.

The meningeal branch (see fig. 13.12) reenters the vertebral canal and innervates the meninges, vertebrae, and spinal ligaments with sensory and motor fibers. The posterior ramus innervates the muscles and joints in that region of the spine and the skin of the back. The larger anterior ramus innervates the anterior and lateral skin and muscles of the trunk, and gives rise to nerves of the limbs.

The anterior ramus differs from one region of the trunk to another. In the thoracic region, it forms an **intercostal nerve**, which travels along the inferior margin of a rib and innervates the skin and intercostal muscles (thus contributing to breathing). Sensory fibers of the intercostal nerve branches to the skin are the most common routes of viral migration in the painful disease known as shingles (see Deeper Insight 13.3). Motor fibers of the intercostal nerves innervate the internal oblique, external oblique, and transverse abdominal muscles. All other anterior rami form the *nerve plexuses*, described next.

²¹ramus = branch

(b) Cross section of the thorax showing innervation of muscles and skin of the chest and back. This section is cut through the intercostal muscles between two ribs.

As shown in figure 13.14, the anterior ramus also gives off a pair of *communicating rami*, which connect with a string of *sympathetic chain ganglia* alongside the vertebral column. These are seen only in spinal nerves T1 through L2. They are components of the sympathetic nervous system and are discussed more fully in chapter 15.

13.2c Nerve Plexuses

Except in the thoracic region, the anterior rami branch and anastomose (merge) repeatedly to form five webs called nerve plexuses: the small **cervical plexus** in the neck, the **brachial plexus** near the shoulder, the **lumbar plexus** of the lower back, the **sacral plexus** immediately inferior to this, and finally, the tiny **coccygeal plexus** adjacent to the lower sacrum and coccyx. A general view of these plexuses is shown in figure 13.11; they are described in the next four tables, beginning with table 13.3. The spinal nerve roots that give rise to each plexus are indicated in brown in each illustration. Some of these roots give rise to smaller branches called *trunks*, *anterior divisions*, *posterior divisions*, and *cords*, which are color-coded and explained in the individual figures. Two of the nerves arising from these plexuses,

the *radial* and *sciatic*, are sites of unique nerve injuries described in Deeper Insight 13.4.

The nerves tabulated here have somatosensory and motor functions. *Somatosensory* means that they carry sensory signals from bones, joints, muscles, and the skin, in contrast to sensory input from the viscera or from special sense organs such as the eyes and ears. Somatosensory signals are for touch, heat, cold, stretch, pressure, pain, and other sensations. One of the most important somatosensory roles of these nerves is proprioception.

The motor function of these nerves is primarily to stimulate the contraction of skeletal muscles. They also innervate the bones of the corresponding regions, and carry autonomic fibers to some viscera and blood vessels, thus adjusting blood flow to local needs.

The following tables identify the areas of skin innervated by the sensory fibers and the muscle groups innervated by the motor fibers of the individual nerves. The muscle tables in chapter 10 provide a more detailed breakdown of the muscles supplied by each nerve and the actions they perform. You may assume that for each muscle, these nerves also carry sensory fibers from its proprioceptors. Throughout these tables, *nerve* is abbreviated *n.* and *nerves* as *nn.*

The Cervical Plexus

The cervical plexus on each side of the neck (**fig. 13.15**) receives fibers from the anterior rami of nerves C1 to C5 and gives rise to the nerves listed in **table 13.3**, in order from superior to inferior. The most important of these are the *phrenic*²² nerves (FREN-ic), which travel

down each side of the mediastinum, innervate the diaphragm, and play an indispensable role in breathing (see fig. 15.3). In addition to the major nerves listed in table 13.3, the cervical plexus gives off several motor branches that innervate the geniohyoid, thyrohyoid, scalene, levator scapulae, trapezius, and sternocleidomastoid muscles.

²²phren = diaphragm

FIGURE 13.15 The Cervical Plexus. **APR**

? Predict the consequences of a surgical accident in which a phrenic nerve is severed.

TABLE 13.3 The Cervical Plexus			
Nerve	Composition	Cutaneous and Other Sensory Innervation	Muscular Innervation (Motor and Proprioceptive)
Lesser occipital n.	Somatosensory	Upper third of medial surface of external ear, skin posterior to ear, posterolateral neck	None
Great auricular n.	Somatosensory	Most of the external ear, mastoid region, region from parotid salivary gland (see fig. 10.7) to slightly inferior to angle of mandible	None
Transverse cervical n.	Somatosensory	Anterior and lateral neck, underside of chin	None
Ansa cervicalis	Motor	None	Omohyoid, sternohyoid, and sternothyroid muscles (see table 10.2)
Supraclavicular nn.	Somatosensory	Lower anterior and lateral neck, shoulder, anterior chest	None
Phrenic n.	Mixed	Diaphragm, pleura, and pericardium	Diaphragm (see table 10.4)

The Brachial Plexus

The **brachial plexus** (figs. 13.16, 13.17) is formed predominantly by the anterior rami of nerves C5 to T1 (C4 and T2 make small contributions). It passes over the first rib into the axilla and innervates the upper limb and some muscles of the neck and shoulder. This plexus is well known for its conspicuous M or W shape seen in cadaver dissections.

The subdivisions of this plexus are called *roots*, *trunks*, *divisions*, and *cords* (color-coded in fig. 13.16). The five **roots** are the anterior rami of C5 through T1. Roots C5 and C6 converge to form the **upper trunk**; C7 continues as the **middle trunk**; and C8 and T1 converge to form the **lower trunk**. Each trunk

divides into an **anterior** and **posterior division**. As the body is dissected from the anterior side of the shoulder inward, the anterior divisions are found in front of the posterior ones. Finally, the six divisions merge to form three large fiber bundles—the **lateral**, **posterior**, and **medial cords**. From these cords arise the five major nerves listed in **table 13.4** in the order of figure 13.16 from superior to inferior.

Among other functions, these nerves carry sensory signals from the skin of the shoulder and upper limb to the spinal cord. **Figure 13.18** shows the regions of the wrist and hand innervated by the sensory fibers of these nerves (except for the axillary nerve, which doesn't extend to the forearm). The motor fibers of these nerves control muscles of the shoulder and upper limb.

FIGURE 13.16 The Brachial Plexus. The labeled nerves innervate muscles tabulated in chapter 10, and those in boldface are further detailed in that table. **APR**

DEEPER INSIGHT 13.3
CLINICAL APPLICATION

Shingles

Chickenpox (*varicella*), a common disease of early childhood, is caused by the *varicella-zoster*²³ virus. It produces an itchy rash that usually clears up with no immediate complications. The virus, however, remains for life in the posterior root ganglia, kept in check by the immune system. If the immune system is compromised, however, the virus can travel along the sensory nerve fibers by *fast axonal transport* (see section 12.2d) and cause **shingles (herpes**²⁴ **zoster)**. The signs of shingles are a painful trail of skin discoloration and fluid-filled vesicles along the path of the nerve (**fig. 13.19**). These usually appear in the chest and waist, often on just one side of the body. The band of affected skin represents the *dermatome* of that nerve, explained shortly (section 13.2d). In some cases, lesions appear on one side of the face, especially in and around the eye, and occasionally in the mouth.

There is no cure, and the vesicles usually heal spontaneously in 1 to 3 weeks. In the meantime, aspirin and steroidal ointments can help to relieve the pain and inflammation of the lesions. Antiviral drugs such as acyclovir can shorten the course of an episode of shingles, but only if taken within the first 2 to 3 days of occurrence. Even after the lesions disappear, however, some people suffer intense pain along the course of the nerve (*postherpetic neuralgia, PHN*), lasting

FIGURE 13.19 Shingles Lesion Tracking the Dermatome of a Sensory Nerve.

Franciscodiazpagador/iStock/Getty Images

for months or even years. PHN is difficult to treat, but pain relievers and antidepressants are of some help. Shingles is particularly common after the age of 50. Childhood vaccination against varicella reduces the risk of shingles later in life. Adult vaccination is recommended in the United States for healthy persons over age 60.

²³*varicella* = little spot; *zoster* = girdle
²⁴*herpes* = creeping

The Lumbar Plexus

The **lumbar plexus** (**fig. 13.20**) is formed from the anterior rami of nerves L1 to L4 and some fibers from T12. With only five roots and two divisions, it is less complex than the brachial plexus. It gives rise to six major nerves, listed in **table 13.5** in anatomically descending order.

The sensory fibers of these nerves carry signals from the hip and knee joints and from skin of the genitalia, lower abdominal and gluteal regions, and the thigh, leg, and foot. The motor fibers control muscles of the hip, thigh, and scrotum.

TABLE 13.5 The Lumbar Plexus			
Nerve	Composition	Cutaneous and Joint Innervation (Sensory)	Muscular Innervation (Motor and Proprioceptive)
Iliohypogastric n.	Mixed	Skin of lower anterior abdominal and posterolateral gluteal regions	Internal and external oblique and transverse abdominal muscles (see table 10.5)
Ilioinguinal n.	Mixed	Skin of upper medial thigh; male scrotum and root of penis; female labia majora	Internal oblique
Genitofemoral n.	Mixed	Skin of middle anterior thigh; male scrotum; female labia majora	Male cremaster muscle (see fig. 27.7)
Lateral femoral cutaneous n.	Somatosensory	Skin of anterior and upper lateral thigh	None
Femoral n.	Mixed	Skin of anterior, medial, and lateral thigh and knee; skin of medial leg and foot; hip and knee joints	Iliacus, pectineus, quadriceps femoris, and sartorius muscles (see tables 10.13, 10.14)
Obturator n.	Mixed	Skin of medial thigh; hip and knee joints	Obturator externus; medial (adductor) thigh muscles (see table 10.13)

FIGURE 13.20 The Lumbar Plexus. **APR**

The Sacral and Coccygeal Plexuses

The **sacral plexus** is formed from the anterior rami of nerves L4, L5, and S1 through S4. It has six roots and anterior and posterior divisions. Since it is connected to the lumbar plexus by fibers that run through the *lumbosacral trunk*, the two plexuses are sometimes referred to collectively as the *lumbosacral plexus*. The **coccygeal plexus** is a tiny plexus formed from the anterior rami of S4, S5, and Co1 (**fig. 13.21**; **table 13.6**).

The *tibial* and *common fibular nerves* travel together through a connective tissue sheath; they are referred to collectively as the **sciatic nerve** (sy-AT-ic), a common focus of injury and pain (see Deeper Insight 13.4). The sciatic nerve passes

through the greater sciatic notch of the hip bone, extends for the length of the thigh, and ends at the popliteal fossa (back of the knee). Here, the tibial and common fibular nerves diverge and follow their separate paths into the leg. The tibial nerve descends through the leg and then gives rise to the *medial* and *plantar nerves* of the foot. The common fibular nerve divides into *deep* and *superficial fibular nerves*.

The sensory fibers of these nerves carry signals from joints of the hip, knee, and foot; from the gluteal and perineal regions and the genitals; and from skin from the gluteal region to the foot. The motor fibers control muscles of the gluteal and perineal regions, thigh, leg, and foot.

FIGURE 13.21 The Sacral and Coccygeal Plexuses.

TABLE 13.6 The Sacral and Coccygeal Plexuses			
Nerve	Composition	Cutaneous and Joint Innervation (Sensory)	Muscular Innervation (Motor and Proprioceptive)
Superior gluteal n.	Mixed	Hip joint	Gluteus minimus, gluteus medius, and tensor fasciae latae muscles (see table 10.13)
Inferior gluteal n.	Mixed	None	Gluteus maximus muscle (see table 10.13)
Posterior cutaneous n.	Somatosensory	Skin of gluteal region, perineum, posterior and medial thigh, popliteal fossa, and upper posterior leg	None
Tibial n.	Mixed	Skin of posterior leg; plantar skin; knee and foot joints	Hamstring muscles; posterior muscles of leg (see tables 10.14, 10.15); most intrinsic foot muscles (via plantar nerves) (see table 10.16)
Fibular (peroneal) nn. (common, deep, and superficial)	Mixed	Skin of anterior distal third of leg, dorsum of foot, and toes I–II; knee joint	Biceps femoris muscle; anterior and lateral muscles of leg; extensor digitorum brevis muscle of foot (see tables 10.14–10.16)
Pudendal n.	Mixed	Skin of penis and scrotum of male; clitoris, labia majora and minora, and lower vagina of female	Muscles of perineum (see table 10.7)

DEEPER INSIGHT 13.4

CLINICAL APPLICATION

Nerve Injuries

The radial and sciatic nerves are especially vulnerable to injury. The radial nerve, which passes through the axilla, may be compressed against the humerus by improperly adjusted crutches, causing *crutch paralysis*. A similar injury often resulted from the now-discredited practice of correcting a dislocated shoulder by putting a foot in a person's armpit and pulling on the arm. One consequence of radial nerve injury is *wrist drop*—the fingers, hand, and wrist are chronically flexed because the extensor muscles supplied by the radial nerve are paralyzed and cannot oppose the flexors.

Because of its position and length, the sciatic nerve of the hip and thigh is the most vulnerable nerve in the body. Trauma to this nerve produces *sciatica*, a sharp pain that travels from the gluteal region along the posterior side of the thigh and leg as far as the ankle. Ninety percent of cases result from a herniated intervertebral disc or osteoarthritis of the lower spine, but sciatica can also be caused by pressure from a pregnant uterus, dislocation of the hip, injections in the wrong area of the buttock, or sitting for a long time on the edge of a hard chair. Some people suffer sciatica because of the habit of sitting on a wallet carried in the hip pocket.

13.2d Cutaneous Innervation and Dermatomes

Each spinal nerve except C1 receives sensory input from a specific area of skin called a **dermatome**.²⁵ A *dermatome map* (fig. 13.22) is a diagram of the cutaneous regions innervated by each spinal nerve. Such a map is oversimplified, however, because the dermatomes overlap at their edges by as much as 50%. Therefore, severance of one sensory nerve root doesn't entirely deaden sensation from a dermatome. It is necessary to sever or anesthetize three sequential spinal nerves to produce a total loss of sensation from one dermatome. Spinal nerve damage is assessed by testing the dermatomes with pinpricks and noting areas in which the patient has no sensation.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- What is meant by the *anterior and posterior roots* of a spinal nerve? Which of these is sensory and which is motor?
- Where are the cell bodies of the posterior root neurons located? Where are the cell bodies of the anterior root neurons located?
- List the five plexuses of spinal nerves and state where each one is located.
- Identify which plexus gives rise to each of the following nerves: axillary, ilioinguinal, obturator, phrenic, pudendal, radial, and sciatic.

FIGURE 13.22 A Dermatome Map of the Anterior Aspect of the Body. Each zone of the skin is innervated by sensory branches of the spinal nerves indicated by the labels. Nerve C1 does not innervate the skin.

²⁵derma = skin; tome = segment, part

13.3 Somatic Reflexes

Expected Learning Outcomes

When you have completed this section, you should be able to

- define *reflex* and explain how reflexes differ from other motor actions;
- describe the general components of a typical reflex arc; and
- explain how the basic types of somatic reflexes function.

Many of us have had our reflexes tested with a little rubber hammer; a tap below the knee produces an uncontrollable jerk of the leg, for example. Testing somatic reflexes is valuable in diagnosing many diseases that cause exaggeration, inhibition, or absence of reflexes—for example, neurosyphilis and other infectious diseases, diabetic neuropathy, multiple sclerosis, alcoholism, hormone and electrolyte imbalances, and lesions of the nervous system.

In this section, we discuss what reflexes are and how they are produced by an assembly of receptors, neurons, and effectors. We also survey the different types of neuromuscular reflexes and how they are important in motor coordination of our everyday tasks.

13.3a The Nature of Reflexes

Reflexes are quick, involuntary, stereotyped reactions of glands or muscles to stimulation. This definition sums up four important properties:

1. Reflexes *require stimulation*—they are not spontaneous actions like muscle tics but responses to sensory input.

2. Reflexes are *quick*—they generally involve only a few interneurons, or none, and minimum synaptic delay.
3. Reflexes are *involuntary*—they occur without intent, often without our awareness, and they're difficult to suppress. Given an adequate stimulus, the response is essentially automatic. You may become conscious of the stimulus that evoked a reflex, and this awareness may enable you to correct or avoid a potentially dangerous situation, but awareness isn't a part of the reflex itself. It may come after the reflex action has been completed, and somatic reflexes can occur even if the spinal cord has been severed so no stimuli reach the brain.
4. Reflexes are *stereotyped*—they occur in essentially the same way every time; the response is very predictable, unlike the variability of voluntary movement.

Reflexes include glandular secretion and contractions of all three types of muscle. The reflexes of skeletal muscle are called **somatic reflexes**, since they involve the somatic nervous system. Chapter 15 concerns the *visceral reflexes* of organs such as the heart and intestines. Somatic reflexes have traditionally been called *spinal reflexes*, but this is a misleading expression for two reasons: (1) Spinal reflexes are not exclusively somatic; visceral reflexes also involve the spinal cord. (2) Some somatic reflexes are mediated more by the brain than by the spinal cord.

A somatic reflex employs a **reflex arc**, in which signals travel along the following pathway (**fig. 13.23**):

- ① *somatic receptors* in the skin, muscles, and tendons;
- ② *afferent nerve fibers*, which carry information from these receptors to the posterior horn of the spinal cord or to the brainstem;

FIGURE 13.23 A Representative Reflex Arc.

- 3 an *integrating center*, a point of synaptic contact between neurons in the gray matter of the cord or brainstem;
- 4 *efferent nerve fibers*, which carry motor impulses to the muscles; and
- 5 *effectors*, the muscles that carry out the response.

In most reflex arcs, the integrating center includes one or more interneurons. Synaptic events in the integrating center determine whether the efferent neurons issue signals to the muscles. The more interneurons there are, the more complex the information processing can be, but with more synapses, there is a longer delay between input and output.

13.3b The Muscle Spindle

Many somatic reflexes involve stretch receptors called **muscle spindles** embedded in the muscles. A muscle spindle is a bundle

of usually seven or eight small, modified muscle fibers enclosed in an elongated fibrous capsule about 5 to 10 mm long (**fig. 13.24**). They're especially concentrated at the ends of a muscle, near its tendons. Muscle spindles are among the body's **proprioceptors**, sense organs specialized to monitor the position and movement of body parts. The function of muscle spindles is to inform the brain of muscle length and body movements. This enables the brain to send motor commands back to the muscles that control muscle tone, posture, coordinated movement, and corrective reflexes (for example, to keep one's balance). Spindles are especially abundant in muscles that require fine control. Hand and foot muscles have 100 or more spindles per gram of muscle, whereas there are fewer in large muscles with coarse movements, and none at all in the middle-ear muscles.

FIGURE 13.24 A Muscle Spindle and Its Innervation.

The modified muscle fibers within the spindle are called **intrafusal²⁶ fibers**, whereas those that make up the rest of the muscle and do its work are called **extrafusal fibers**. (Be careful not to confuse these terms with nerve fibers.) Each end of an intrafusal fiber has a few sarcomeres. A **gamma motor neuron** of the spinal cord innervates each end and stimulates its contraction. This maintains tension and sensitivity of the intrafusal fiber, preventing it from going slack like an unstretched rubber band when a muscle shortens. Spinal motor neurons that supply the extrafusal muscle fibers are called **alpha motor neurons**. Up to now, we have studied only that type and the neuromuscular junctions they form with muscle, but nearly one-third of all spinal motor neurons are the gamma type—evidence of the great importance of muscle spindles.

The long midportion of an intrafusal fiber lacks sarcomeres and cannot contract, but is supplied by two types of sensory nerve fibers: *primary afferent fibers* that monitor muscle length and how rapidly it changes, which are therefore very responsive to sudden body movements; and *secondary afferent fibers* that monitor length only, not rate of change. Both of these sensory fiber types enter the posterior horn of the spinal cord, synapse on the alpha motor neurons and regulate their firing, and also send branches up the spinal cord to the brain. Through these nerve fibers, the brain constantly but subconsciously monitors the length and tension of nearly every skeletal muscle throughout the body. This input is vital to the maintenance of posture, fine control of movements, and corrective reflexes.

Suppose, for example, you are standing on the deck of a boat that is gently rocking on the waves. At one moment, your body begins to tip forward. This stretches your calf muscles and their muscle spindles, setting off sensory signals to the spinal cord. The CNS responds to this by tensing your calf muscles to keep you from falling and to restore or maintain your upright posture. Then the boat rocks the other way and you begin to tip to the rear. The spindles in the calf muscles are now compressed and their signaling rate drops. Such input from the spindles inhibits the alpha motor neurons of the calf muscles, relaxing those muscles so they don't pull you farther backward. At the same time, your backward tilt stretches spindles in your anterior leg and thigh muscles, leading to their contraction and preventing you from falling over backward.

You can well imagine the importance of these reflexes to the coordination of such common movements as walking and dancing. In more subtle ways, all day long, your brain monitors input from the spindles of opposing muscles and makes fine adjustments in muscle tension to maintain your posture and coordination.

13.3c The Stretch Reflex

When a muscle is suddenly stretched, it “fights back”—it contracts, increases tone, and feels stiffer than an unstretched muscle. This response, called the **stretch (myotatic²⁷) reflex**, helps to maintain equilibrium and posture, as we just saw in the rocking boat example. To take another case, if your head starts to tip forward, it stretches muscles at the back of your neck. This stimulates their muscle spindles, which send signals to the cerebellum by way of the brainstem. The

cerebellum integrates this information and relays it to the cerebral cortex, and the cortex sends signals back, via the brainstem, to the muscles. The muscles contract and raise your head. Continual, subtle adjustments in this reflex arc keep your head generally erect throughout most of your waking hours.

Stretch reflexes often feed back not to a single muscle but to a set of synergists and antagonists. Since the contraction of a muscle on one side of a joint stretches the antagonist on the other side, the flexion of a joint creates a stretch reflex in the extensors, and extension creates a stretch reflex in the flexors. (Think of the way your biceps brachii is stretched when you extend your elbow, for example.) Consequently, stretch reflexes stabilize the joints by balancing the tension of extensors and flexors. They also dampen (smooth out) muscle action. Without stretch reflexes, a person's movements tend to be jerky. Stretch reflexes are especially important in coordinating vigorous and precise movements such as dance.

A stretch reflex is mediated primarily by the brain and is not, therefore, strictly a spinal reflex, but a weak component of it is spinal and occurs even if the spinal cord is severed from the brain. The spinal component can be more pronounced if a muscle is stretched suddenly. This occurs in the reflexive contraction of a muscle when its tendon is tapped, as in the familiar *patellar (knee-jerk) reflex*. Tapping the patellar ligament with a reflex hammer abruptly stretches the quadriceps femoris muscle of the thigh (**fig. 13.25**). This stimulates numerous muscle spindles in the quadriceps and sends an intense volley of signals to the spinal cord, mainly by way of primary afferent nerve fibers.

In the spinal cord, these nerve fibers synapse directly with the alpha motor neurons that return to the muscle, thus forming **mono-synaptic reflex arcs**. That is, there is only one synapse between the afferent and efferent neuron, so there is little synaptic delay and a very prompt response. The alpha motor neurons excite the quadriceps, making it contract and creating the knee jerk.

There are many other tendon reflexes. A tap on the calcaneal tendon causes plantar flexion of the foot, a tap on the triceps brachii tendon causes extension of the elbow, and a tap on the masseter causes clenching of the jaw.

Stretch reflexes and other muscle contractions often depend on **reciprocal inhibition**, a reflex that prevents muscles from working against each other by inhibiting antagonists. In the knee jerk, for example, the quadriceps wouldn't produce much joint movement if its antagonists, the hamstring muscles, contracted at the same time. But reciprocal inhibition prevents that from happening. Some branches of the sensory nerve fibers from the quadriceps muscle spindles stimulate spinal interneurons that, in turn, *inhibit* the alpha motor neurons of the hamstrings (**fig. 13.25**). The hamstrings remain relaxed and allow the quadriceps to extend the knee.

13.3d The Flexor (Withdrawal) Reflex

A **flexor reflex** is the quick contraction of flexor muscles resulting in the withdrawal of a limb from an injurious stimulus. For example, suppose you are wading in a lake and step on a broken bottle with your right foot (**fig. 13.26**). Even before you are consciously

²⁶*intra* = within; *fus* = spindle

²⁷*myo* = muscle; *tat* (from *taxis*) = stretch

FIGURE 13.25 The Patellar Tendon Reflex Arc and Reciprocal Inhibition of the Antagonistic Muscle. Plus signs indicate excitation of a postsynaptic cell (EPSP), and the minus sign indicates inhibition (IPSP). The tendon reflex occurs in the quadriceps femoris muscle, while the hamstring muscles exhibit reciprocal inhibition so they don't contract and oppose the quadriceps.

? Why is no IPSP shown at point 7 if the contraction of this muscle is being inhibited?

aware of the pain, you quickly pull your foot away before the glass penetrates any deeper. This action involves contraction of the flexors and relaxation of the extensors in that limb; the latter is another case of reciprocal inhibition.

The protective function of this reflex requires more than a quick jerk like a tendon reflex, so it involves more complex neural pathways. Sustained contraction of the flexors is produced by a parallel after-discharge circuit in the spinal cord (see fig. 12.32). This circuit is part of a **polysynaptic reflex arc**—a pathway in which signals travel over many synapses on their way back to the muscle. Some signals follow routes with only a few synapses and return to the flexor muscles quickly. Others follow routes with more synapses, and therefore more delay, so they reach the flexor muscles a little later. Consequently, the flexor muscles receive prolonged output from the spinal cord and not just one sudden stimulus as in a stretch reflex. By the time these efferent signals begin to die out, you will probably be consciously aware of the pain and begin taking voluntary action to prevent further harm.

13.3e The Crossed Extension Reflex

In the preceding situation, if *all* you did was to quickly lift the injured leg from the lake bottom, you would fall over. To prevent this and

maintain your balance, other reflexes shift your center of gravity over the leg that is still planted on the ground. The **crossed extension reflex** is the contraction of extensor muscles in the limb opposite from the one that is withdrawn (fig. 13.26). It extends and stiffens that limb and enables you to keep your balance. To produce this reflex, branches of the afferent nerve fibers cross from the stimulated side of the body to the contralateral side of the spinal cord. There, they synapse with interneurons, which, in turn, excite or inhibit alpha motor neurons to the muscles of the contralateral limb.

In the ipsilateral leg (the side that was hurt), you would contract your flexors and relax your extensors to lift the leg from the ground. On the contralateral side, you would relax your flexors and contract the extensors to stiffen that leg, since it must suddenly support your entire body. At the same time, signals travel up the spinal cord and cause contraction of contralateral muscles of the hip and abdomen, such as your internal and external obliques, to shift your center of gravity over the extended leg. To a large extent, the coordination of all these muscles and maintenance of equilibrium are mediated by the cerebellum and cerebral cortex.

The flexor reflex employs an **ipsilateral reflex arc**—one in which the sensory input and motor output are on the same side of the spinal cord. The crossed extension reflex employs a **contralateral reflex arc**, in which the input and output are on opposite sides. An

FIGURE 13.26 The Flexor and Crossed Extension Reflexes. A pain stimulus triggers a withdrawal reflex, which results in contraction of flexor muscles of the injured limb. At the same time, a crossed extension reflex results in contraction of extensor muscles of the opposite limb. The latter reflex aids in balance when the injured limb is raised. Note that for each limb, while the agonist contracts, the alpha motor neuron to its antagonist is inhibited, as indicated by the red minus signs in the spinal cord. **APR**

? Would you expect this reflex arc to show more synaptic delay, or less, than the ones in figure 13.25? Why?

intersegmental reflex arc is one in which the input and output occur at different levels (segments) of the spinal cord—for example, when pain to the foot causes contractions of abdominal and hip muscles higher up the body. Note that all of these reflex arcs can function simultaneously to produce a coordinated protective response to pain.

▶▶▶ APPLY WHAT YOU KNOW

Serial and parallel processing are described in section 12.6d. Which of these do you think best describes the stretch reflex, flexor reflex, and crossed extension reflex? Explain.

13.3f The Tendon Reflex

Tendon organs are proprioceptors located in a tendon near its junction with a muscle (**fig. 13.27**). A tendon organ is about 0.5 mm long. It consists of an encapsulated bundle of small, loose collagen fibers and one or more nerve fibers that penetrate the capsule and end in flattened leaflike processes between the collagen fibers. As long as the tendon is slack, its collagen fibers are slightly spread and put little pressure on the nerve endings. When muscle contraction pulls on the tendon, the collagen fibers come together like the two sides of a stretched rubber band and squeeze the nerve endings

FIGURE 13.27 A Tendon Organ.

between them. The nerve fiber sends signals to the spinal cord that provide the CNS with feedback on the degree of muscle tension at the joint.

The **tendon reflex** is a response to excessive tension on the tendon. It inhibits alpha motor neurons to the muscle so the muscle

doesn't contract as strongly. This moderates muscle contraction before it tears a tendon or pulls it loose from the muscle or bone. Nevertheless, strong muscles and quick movements sometimes damage a tendon before the reflex can occur, causing such athletic injuries as a ruptured calcaneal tendon.

The tendon reflex also functions when some parts of a muscle contract more than others. It inhibits the muscle fibers connected with overstimulated tendon organs so their contraction is more comparable to the contraction of the rest of the muscle. This spreads the workload more evenly over the entire muscle, which is beneficial in such actions as maintaining a steady grip on a tool or the rung of a ladder.

Table 13.7 and Deeper Insight 13.5 describe some injuries and other disorders of the spinal cord and spinal nerves.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

10. Name five structural components of a typical somatic reflex arc. Which of these is absent from a monosynaptic arc?
11. State the function of each of the following in a muscle spindle: intrafusal fibers, gamma motor neurons, and primary afferent fibers.
12. Explain how nerve fibers in a tendon sense the degree of tension in a muscle.
13. Why must the withdrawal reflex, but not the stretch reflex, involve a polysynaptic reflex arc?
14. Explain why the crossed extension reflex must accompany a withdrawal reflex of the leg.

TABLE 13.7 Some Disorders of the Spinal Cord and Spinal Nerves

Guillain–Barré syndrome (gee-LANE ba-RAY)	An acute demyelinating nerve disorder often triggered by viral infection, resulting in muscle weakness, elevated heart rate, unstable blood pressure, shortness of breath, and sometimes death from respiratory paralysis
Neuralgia	General term for nerve pain, often caused by pressure on spinal nerves from herniated intervertebral discs
Paresthesia	Abnormal sensations of prickling, burning, numbness, or tingling in the absence of actual stimulation; a symptom of peripheral nerve disorders
Peripheral neuropathy	Any loss of sensory or motor function due to nerve injury; also called <i>nerve palsy</i>
Rabies (hydrophobia)	A disease usually contracted from animal bites, involving viral infection that spreads via somatic motor nerve fibers to the CNS and then autonomic nerve fibers; leads to seizures, coma, and death; invariably fatal if not treated before CNS symptoms appear
Spinal meningitis	Inflammation of the spinal meninges due to viral, bacterial, or other infection

You can find other spinal cord and peripheral nerve disorders described in the following places:

Carpal tunnel syndrome in Deeper Insight 10.5; *multiple sclerosis* and *Tay–Sachs disease* in Deeper Insight 12.2; *polio* and *amyotrophic lateral sclerosis* in Deeper Insight 13.2; *shingles* in Deeper Insight 13.3; *crutch paralysis* and *sciatica* in Deeper Insight 13.4; spinal cord trauma and the forms of paralysis in Deeper Insight 13.5; *leprosy* and *diabetic neuropathy* in section 16.2d, and the latter also in section 17.7e.

DEEPER INSIGHT 13.5

CLINICAL APPLICATION

Spinal Cord Trauma

In the United States, almost 18,000 people are newly paralyzed each year by spinal cord trauma, usually as a result of vertebral fractures. The greatest incidence is among males over 40 years old, usually because of high-risk behaviors. Nearly three-quarters of cases are from vehicular accidents and falls. Elderly people are also at above-average risk because of falls, and in times of war, battlefield injuries account for many cases.

Effects of Injury

Complete *transection* (severance) of the spinal cord causes immediate loss of motor control at and below the level of the injury. Transection superior to segment C4 presents a threat of respiratory failure. Victims also lose sensation from the level of injury and below, although some patients temporarily feel burning pain within one or two dermatomes of the level of the lesion.

In the early stage, victims exhibit a syndrome called *spinal shock*. Muscles below the level of injury exhibit flaccid paralysis (inability to contract) and an absence of reflexes because of the lack of stimulation from higher levels of the CNS. For 8 days to 8 weeks after the accident, the injured person typically lacks bladder and bowel reflexes and thus retains urine and feces. Lacking sympathetic stimulation to the blood vessels, the person may exhibit *neurogenic shock* in which the vessels dilate and blood pressure drops dangerously low. Fever may occur because the hypothalamus cannot induce sweating to cool the body. Spinal shock can last from a few days to several weeks (usually 7 to 20 days).

As spinal shock subsides, somatic reflexes begin to reappear, at first in the toes and progressing to the feet and legs. Autonomic reflexes also reappear. Contrary to the earlier urinary and fecal retention, one now has the opposite problem, incontinence, as the rectum and bladder empty reflexively in response to stretch. Both the somatic and autonomic nervous systems typically exhibit exaggerated reflexes, a state called *hyperreflexia* or the *mass reflex reaction*. Stimuli such as a full bladder or cutaneous touch can trigger an extreme cardiovascular reaction. The systolic blood pressure, normally about 120 mm Hg, jumps to as high as 300 mm Hg. This causes intense headaches and sometimes a stroke. Pressure receptors in the major arteries sense this rise in blood pressure and activate a reflex that slows the heart, sometimes to a rate as low as 30 or 40 beats/minute (*bradycardia*), compared with a normal rate of 70 to 80. One may also experience profuse sweating and blurred vision.

Males at first lose the capacity for erection and ejaculation. They may recover these functions later and become capable of ejaculating and fathering children, but without sexual sensation. In females, menstruation may become irregular or cease.

The most serious permanent effect of spinal cord trauma is paralysis. The flaccid paralysis of spinal shock later changes to spastic paralysis as spinal reflexes are regained but lack inhibitory control from the brain. Spastic paralysis typically starts with chronic flexion of the hips and knees (flexor spasms) and progresses to a state in which the limbs become straight and rigid (extensor spasms). Three forms of muscle paralysis are **paraplegia**, a paralysis of both lower limbs resulting from spinal cord lesions at levels T1 to L1; **quadriplegia**, the paralysis of all four limbs resulting from lesions above level C5; and **hemiplegia**, paralysis of one side of the body, usually resulting not from spinal cord injuries but from a stroke or other brain lesion. Spinal cord lesions from C5 to C7

can produce a state of partial quadriplegia—total paralysis of the lower limbs and partial paralysis (*paresis*, or weakness) of the upper limbs.

Pathogenesis

Spinal cord trauma produces two stages of tissue destruction. The first is instantaneous—the destruction of cells by the traumatic event itself. The second stage, a wave of tissue death by necrosis and apoptosis, begins in minutes and lasts for days. It is far more destructive than the initial injury, typically converting a lesion in one spinal cord segment to a lesion that spans four or five segments, two above and two below the original site.

Microscopic hemorrhages appear in the gray matter and pia mater within minutes and grow larger over the next 2 hours. The white matter becomes edematous (swollen). Hemorrhaging and edema spread to adjacent segments of the cord and can fatally affect respiration or brainstem function when it occurs in the cervical region. *Ischemia* (iss-KEE-me-uh), the lack of blood, quickly leads to necrosis. The white matter regains circulation in about 24 hours, but the gray matter remains ischemic. Inflammatory cells (leukocytes and macrophages) infiltrate the lesion as the circulation recovers, and while they clean up necrotic tissue, they also contribute to the damage by releasing destructive free radicals and other toxic chemicals. The necrosis worsens, and is accompanied by another form of cell death, apoptosis. Apoptosis of the spinal oligodendrocytes, the myelinating glial cells of the CNS, results in demyelination of spinal nerve fibers, followed by death of the neurons.

In as little as 4 hours, this second wave of destruction, called *post-traumatic infarction*, consumes about 40% of the cross-sectional area of the spinal cord; within 24 hours, it destroys 70%. As many as five segments of the cord become transformed into a fluid-filled cavity, which is replaced with collagenous scar tissue over the next 3 to 4 weeks. This scar is one of the obstacles to the regeneration of lost nerve fibers.

Treatment

The first priority in treating a spinal injury patient is to immobilize the spine to prevent further trauma. Respiratory or other life support may also be required. Methylprednisolone, a steroid, dramatically improves recovery. Given within 3 hours of the trauma, it reduces injury to cell membranes and inhibits inflammation and apoptosis.

After these immediate requirements are met, reduction (repair) of the fracture is important. If a CT or MRI scan indicates spinal cord compression by the vertebral canal, a *decompression laminectomy* may be performed, in which vertebral laminae are removed from the affected region. CT and MRI have helped a great deal in recent decades for assessing vertebral and spinal cord damage, guiding surgical treatment, and improving recovery. Physical therapy is important for maintaining muscle and joint function as well as promoting the patient's psychological recovery.

Treatment strategies for spinal cord injuries are a vibrant field of contemporary medical research. Some current interests are the use of antioxidants to reduce free radical damage, and the implantation of pluripotent stem cells, which has produced significant (but not perfect) recovery from spinal cord lesions in rats. Public hopes have often been raised by promising studies in the scientific literature and news media, only to be dashed by the inability of other laboratories to repeat and confirm the results.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

13.1 The Spinal Cord

1. Functions of the spinal cord
2. Skeletal landmarks that mark the extent of the adult spinal cord, and what occupies the vertebral canal inferior to the spinal cord
3. The four regions of the spinal cord and the basis for their names
4. What defines one segment of the cord
5. Two enlargements of the cord and why the cord is wider at these points
6. Names and structures of the three spinal meninges, in order from superficial to deep, and the relationships of the epidural and subarachnoid spaces to the meninges
7. The two types of ligaments that arise from the pia mater; where they are found and what purpose they serve
8. Organization of spinal gray and white matter as seen in cross sections of the cord; how gray and white matter differ in composition; and why they are called *gray* and *white matter*
9. The position of the posterior and anterior horns of the gray matter; where lateral horns are also found, and the functions of all three
10. The anatomical basis for dividing white matter into three funiculi on each side of the cord, and for dividing each funiculus into tracts
11. Names and functions of the ascending tracts of the spinal cord
12. The meanings of *first-* through *third-order* neurons in an ascending tract

13. Names and functions of the descending tracts
14. The locations and distinctions between upper and lower motor neurons in the descending tracts
15. Decussation and its implications for cerebral function in relation to sensation and motor control of the lower body, and for the effects of a stroke
16. What it means to say that the origin and destination of a tract, or any two body parts, are ipsilateral or contralateral

13.2 The Spinal Nerves

1. Structure of a nerve, especially the relationship of the endoneurium, perineurium, and epineurium to nerve fibers and fascicles
2. The basis for classifying nerve fibers as afferent or efferent, somatic or visceral, and special or general
3. The basis for classifying entire nerves as sensory, motor, or mixed
4. The definition and structure of a *ganglion*
5. The number of spinal nerves and their relationship to the spinal cord and intervertebral foramina
6. Anatomy of the posterior and anterior roots of a spinal nerve; the rootlets; and the posterior root ganglion
7. Anatomy of the anterior ramus, posterior ramus, and meningeal branch of a spinal nerve
8. What arises from the anterior ramus in the thoracic region as opposed to all other regions of the spinal cord
9. General structure of a spinal nerve plexus and the names and locations of the five plexuses

10. Distinctions between the roots, trunks, anterior and posterior divisions, and cords of a spinal nerve plexus; which of these five features occur in each of the five plexuses
11. Nerves that arise from each plexus and the body regions or structures to which each nerve provides sensory innervation, motor innervation, or both
12. Dermatomes and why they are relevant to the clinical diagnosis of nerve disorders

13.3 Somatic Reflexes

1. Four defining criteria of a reflex; how somatic reflexes differ from other types; and the flaw in calling somatic reflexes spinal reflexes
2. The pathway and constituents of a somatic reflex arc
3. The role of proprioceptors in somatic reflexes
4. Structure and function of muscle spindles
5. Stretch reflexes; one or more examples; the purpose they serve in everyday function; the mechanism of a stretch reflex; and an anatomical reason why stretch reflexes are often quicker than other types of somatic reflexes
6. Reciprocal inhibition and why it is important that it often accompany a stretch reflex
7. Flexor reflexes; a common purpose that they serve; and why it is beneficial for flexor reflexes to employ polysynaptic reflex arcs
8. Crossed extension reflexes and why it is important for this type of reflex to accompany a withdrawal reflex
9. The structure, location, and function of a tendon organ

STUDY GUIDE

▶ Testing Your Recall

Answers in Appendix A

- Below L2, the vertebral canal is occupied by a bundle of spinal nerve roots called
 - the terminal filum.
 - the descending tracts.
 - the gracile fasciculus.
 - the medullary cone.
 - the cauda equina.
- The brachial plexus gives rise to all of the following nerves *except*
 - the axillary nerve.
 - the radial nerve.
 - the obturator nerve.
 - the median nerve.
 - the ulnar nerve.
- Nerve fibers that adjust the tension in a muscle spindle are called
 - intrafusal fibers.
 - extrafusal fibers.
 - alpha motor neurons.
 - gamma motor neurons.
 - primary afferent fibers.
- A stretch reflex requires the action of _____ to prevent an antagonistic muscle from interfering with the agonist.
 - gamma motor neurons
 - a withdrawal reflex
 - a crossed extension reflex
 - reciprocal inhibition
 - a contralateral reflex
- A patient has a gunshot wound that caused a bone fragment to nick the spinal cord. The patient now feels no pain or temperature sensations from that level of the body down. Most likely, the _____ was damaged.
 - gracile fasciculus
 - medial lemniscus
 - tectospinal tract
 - lateral corticospinal tract
 - spinothalamic tract
- Which of these is *not* a region of the spinal cord?
 - cervical
 - thoracic
 - pelvic
 - lumbar
 - sacral
- In the spinal cord, the cell bodies of the lower motor neurons are found in
 - the cauda equina.
 - the posterior horns.
 - the anterior horns.
 - the posterior root ganglia.
 - the fasciculi.
- The outermost connective tissue wrapping of a nerve is called the
 - epineurium.
 - perineurium.
 - endoneurium.
 - arachnoid mater.
 - dura mater.
- The intercostal nerves between the ribs arise from which spinal nerve plexus?
 - cervical
 - brachial
 - lumbar
 - sacral
 - none of them
- All somatic reflexes share all of the following properties *except*
 - they are quick.
 - they are monosynaptic.
 - they require stimulation.
 - they are involuntary.
 - they are stereotyped.
- Outside the CNS, the cell bodies of neurons are clustered in swellings called _____.
- Distal to the intervertebral foramen, a spinal nerve branches into an anterior and posterior _____.
- The cerebellum receives feedback from the muscles and joints by way of the _____ tracts of the spinal cord.
- In the _____ reflex, contraction of flexor muscles in one limb is accompanied by the contraction of extensor muscles in the contralateral limb.
- Modified muscle fibers serving primarily to detect stretch are called _____.
- The _____ nerves arise from the cervical plexus and innervate the diaphragm.
- The crossing of a nerve fiber or tract from the right side of the CNS to the left, or vice versa, is called _____.
- The nonvisual awareness of the body's position and movements is called _____.
- The _____ ganglion contains the cell bodies of neurons that carry sensory signals to the spinal cord.
- The sciatic nerve is a composite of two nerves: the _____ and _____.

▶ Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|-------------|------------|-------------|
| 1. arachno- | 3. contra- | 7. pia |
| 2. caudo- | 4. cune- | 8. proprio- |
| | 5. ipsi- | 9. ram- |
| | 6. phreno- | 10. tecto- |

STUDY GUIDE

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

1. The gracile fasciculus is a descending spinal tract.
2. The adult spinal cord terminates in the sacral canal.
3. Each spinal nerve rootlet is connected to its own segment of the spinal cord.
4. Some spinal nerves are sensory and others are motor.
5. The dura mater adheres tightly to the bone of the vertebral canal.
6. The anterior and posterior horns of the spinal cord are composed of white matter.
7. The corticospinal tracts carry sensory signals from the spinal cord to the cerebral cortex.
8. The dermatomes are nonoverlapping regions of skin innervated by different spinal nerves.
9. Somatic reflexes are those that do not involve the brain.
10. Ipsilateral reflex arcs are monosynaptic, whereas contralateral arcs are polysynaptic.

► Testing Your Comprehension

1. Jillian is thrown from a horse. She strikes the ground with her chin, causing severe hyperextension of the neck. Emergency medical technicians properly immobilize her neck and transport her to a hospital, but she dies 5 minutes after arrival. An autopsy shows multiple fractures of vertebrae C1, C6, and C7 and extensive damage to the spinal cord. Explain why she died rather than being left quadriplegic.
2. Wallace is the victim of a hunting accident. A bullet grazed his vertebral column, and bone fragments severed the left half of his spinal cord at segments T8 through T10. Since the accident, Wallace has had a condition called *dissociated sensory loss*, in which he feels no sensations of deep touch or limb position on the *left* side of his body below the injury, and no sensations of pain or heat from the *right* side. Explain what spinal tract(s) the injury has affected and why these sensory losses are on opposite sides of the body.
3. Anthony gets into a fight between rival gangs. As an attacker comes at him with a knife, he turns to flee, but stumbles. The attacker stabs him on the medial side of the right gluteal fold and Anthony collapses. He loses all use of his right limb, being unable to extend his hip, flex his knee, or move his foot. He never fully recovers these lost functions. Explain what nerve injury Anthony has most likely suffered.
4. Stand with your right shoulder, hip, and foot firmly against a wall. Raise your left foot from the floor without losing contact with the wall at any point. What happens? Why? What principle of this chapter does this demonstrate?
5. When a patient needs a tendon graft, surgeons sometimes use the tendon of the palmaris longus, a relatively dispensable muscle of the forearm. The median nerve lies nearby and looks very similar to this tendon. There have been cases in which a surgeon mistakenly removed a section of this nerve instead of the tendon. What effects do you think such a mistake would have on the patient?

THE BRAIN AND CRANIAL NERVES

Diffusion tensor image of white matter tracts in a lateral view of the brain

Module 7: Nervous System

BRUSHING UP

- The anatomy of the brain and cranial nerves is, in many respects, described in relation to the skull. Therefore, it may be helpful to review the cranial bones and major foramina in section 8.2a.
- You must be familiar with neuron structure (see section 12.2c) and with glial cells and their functions (see section 12.3a).
- The brainstem contains extensions of the spinal cord tracts, so you will find it helpful to know those or refer back to table 13.1 as you study the brainstem.
- Understanding several facets of brain and cranial nerve function will call upon your knowledge of proprioception, defined in section 13.1e.
- Understanding sensory and motor relations between the brain and lower body, including the effects of stroke, depends on your understanding of decussation in neural pathways (section 13.1e).
- To best understand the cranial nerves, you should be familiar with the general structure of nerves and ganglia, afferent and efferent nerve fibers, and the distinction between sensory, motor, and mixed nerves (see section 13.2a).

The human brain has a high opinion of itself, often claiming to be the most complex object in the known universe. It would be hard to argue otherwise. It has a mystique that intrigues modern biologists and psychologists even as it did the philosophers of antiquity. Aristotle thought it was just a radiator for cooling the blood, but generations earlier, Hippocrates had expressed a more accurate view. “Men ought to know,” he said, “that from the brain, and from the brain only, arise our pleasures, joy, laughter and jests, as well as our sorrows, pains, griefs and tears. Through it, in particular, we think, see, hear, and distinguish the ugly from the beautiful, the bad from the good, the pleasant from the unpleasant.”

Brain function is so strongly associated with what it means to be alive and human that the cessation of brain activity is taken as a clinical criterion of death even when other organs of the body are still functioning. With its hundreds of neural pools and trillions of synapses, the brain performs sophisticated tasks beyond our present understanding. Still, all of our mental functions, no matter how complex, are ultimately based on the cellular activities described in chapter 12. The relationship of the mind and personality to the cellular function of the brain is a question that will provide fertile ground for scientific study and philosophical debate long into the future.

This chapter is a study of the brain and the cranial nerves directly connected to it. Here we will plumb some of the mysteries of motor control, sensation, emotion, thought, language, personality, memory, dreams, and plans. Brain circuitry and function easily fill many books the size of this one, and we can barely scratch the surface of this complex subject here. This coverage will, however, provide some intriguing insights and lay a foundation for further study in other courses.

14.1 Overview of the Brain

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the major subdivisions and anatomical landmarks of the brain;
- describe the locations of its gray and white matter; and
- describe the embryonic development of the CNS and relate this to adult brain anatomy.

In the evolution of the central nervous system from the simplest vertebrates to humans, the spinal cord changed very little while the brain changed a great deal. In fishes and amphibians, the brain weighs about the same as the spinal cord, but in humans, it weighs 55 times as much. It averages about 1,300 g (2.9 lb) in men and 1,200 g in women, and has an estimated 75 to 125 billion neurons. The difference between the sexes is proportional to body size, not intelligence. The Neanderthal people had larger brains than modern humans do.

Ours is the most sophisticated brain when compared to others in awareness of the environment, adaptability to environmental variation and change, quick execution of complex decisions, fine motor control and mobility of the body, ability to foresee and plan for the future, and behavioral complexity. Over the course of human evolution, it has shown its greatest growth in areas concerned with vision, memory, abstract thought, and motor control of the prehensile hand.

14.1a Major Landmarks

We begin with a general overview of the major landmarks of the brain. These provide important reference points for the more detailed study to come.

Two directional terms used in descriptions of CNS anatomy are *rostral* and *caudal*. **Rostral**¹ means “toward the nose” and **caudal**² means “toward the tail.” These are apt descriptions for an animal such as a laboratory rat, on which so much brain research has been done. The terms are retained for human neuroanatomy as well, but in references to the brain, *rostral* means “toward the forehead” and *caudal* means “toward the spinal cord.” In the spinal cord and brainstem, which are vertically oriented, *rostral* means “higher” and *caudal* means “lower.”

We can conceptually divide the brain into three major portions—the *forebrain*, *cerebellum*, and *brainstem*. The most prominent part of the forebrain is the **cerebrum** (seh-REE-brum or SER-eh-brum). It constitutes about 83% of the brain’s volume and consists mainly of a pair of half globes called the **cerebral hemispheres** (fig. 14.1a). Each hemisphere is marked by thick folds called **gyri**³ (JY-rye; singular, *gyrus*) separated by shallow grooves called **sulci**⁴ (SUL-sye;

¹*rostr* = nose

²*caud* = tail

³*gyr* = turn, twist

⁴*sulc* = furrow, groove

FIGURE 14.1 Surface Anatomy of the Brain. (a) Superior view of the cerebral hemispheres. (b) Left lateral view. (c) Lateral view of the cadaver brain. **APR**

c: Rebecca Gray/Wise Anatomy Collection/McGraw Hill

singular, *sulcus*). A deep median groove, the **longitudinal cerebral fissure**, separates the right and left hemispheres from each other. At the bottom of this fissure, the hemispheres are connected by a thick bundle of nerve fibers called the **corpus callosum**⁵—a prominent landmark for anatomical description with a distinctive C shape in sagittal section (**fig. 14.2**). A smaller portion of the forebrain called the **diencephalon** underlies the cerebrum medially.

The **cerebellum**⁶ (SER-eh-BEL-um) is the second-largest part of the brain. It occupies the posterior cranial fossa inferior to the cerebrum, separated from it by the **transverse cerebral fissure** (**fig. 14.1b, c**; also see **fig. 8.9**). It is also marked by fissures, sulci, and gyri (called *folia* in the cerebellum).

The **brainstem** is all of the brain except the forebrain and cerebellum. Its components, from rostral to caudal, are the *midbrain*, *pons*, and *medulla oblongata* (**fig. 14.2**). Caudally, the brainstem ends at the foramen magnum of the skull; the CNS continues below this as the spinal cord. In a living person, the brainstem is oriented like a vertical stalk with the forebrain perched on top like a mushroom cap. Postmortem changes give it a more oblique angle in the cadaver and, consequently, in many medical illustrations.

14.1b Gray and White Matter

The brain, like the spinal cord, is composed of gray and white matter (see **figs. 14.5, 14.6c**). Gray matter—the seat of the nerve cell bodies, dendrites, and synapses—forms a surface layer called the **cortex** over the cerebrum and cerebellum, and deeper masses called **nuclei** surrounded by white matter. In the context of neuroanatomy, *nucleus* means a cluster or network of neurons dedicated to a specific function, ranging from hunger and hearing to emotions and sleep. You could think of neural nuclei as analogous to the microchips in a complex electronic device.

White matter lies deep to the cortical gray matter in most of the brain, opposite from the relationship of gray and white matter in the spinal cord. As in the spinal cord, white matter is composed of **tracts**, or bundles of nerve fibers (axons), which here connect one part of the brain to another and to the spinal cord. These are described later in more detail.

14.1c Embryonic Development

Mature brain anatomy is often described in terms of *forebrain*, *midbrain*, and *hindbrain*—three terms that can be fully appreciated only with some awareness of the embryonic development of the CNS.

The nervous system develops from ectoderm, the outermost tissue layer of an embryo. Within the first 3 weeks, the embryo undergoes a process called **neurulation**. A *neural plate* forms along the dorsal midline of the embryo and sinks into the tissues to form a *neural groove*, with a raised *neural fold* along each side (**fig. 14.3**). The neural folds roll toward each other and fuse, somewhat like a

closing zipper, beginning in the cervical region and progressing both caudally and rostrally. By day 26, this process creates a hollow channel called the **neural tube**. Following closure, the neural tube separates from the overlying ectoderm, sinks a little deeper, and grows lateral processes that later form motor nerve fibers. The lumen of the neural tube becomes a fluid-filled space that later constitutes the *central canal* of the spinal cord and *ventricles* of the brain.

As the neural tube develops, some ectodermal cells that originally lay along the margin of the groove separate from the rest and form a longitudinal column on each side called the **neural crest**. Neural crest cells give rise to the two inner meninges (arachnoid mater and pia mater); most of the peripheral nervous system, including the sensory and autonomic nerves and ganglia and Schwann cells; and some other structures of the skeletal, integumentary, and endocrine systems.

By the fourth week, the neural tube exhibits three anterior dilations, or *primary vesicles*, called the **forebrain** (*prosencephalon*⁷) (PROSS-en-SEF-uh-lon), **midbrain** (*mesencephalon*⁸) (MES-en-SEF-uh-lon), and **hindbrain** (*rhombencephalon*⁹) (ROM-ben-SEF-uh-lon) (**fig. 14.4**). By the fifth week, it subdivides into five *secondary vesicles*. The forebrain divides into two of them, the **telencephalon**¹⁰ (TEL-en-SEFF-uh-lon) and **diencephalon**¹¹ (DY-en-SEF-uh-lon); the midbrain remains undivided and retains the name **mesencephalon**; and the hindbrain divides into two vesicles, the **metencephalon**¹² (MET-en-SEF-uh-lon) and **myelencephalon**¹³ (MY-el-en-SEF-uh-lon). The telencephalon has a pair of lateral outgrowths that later become the cerebral hemispheres. The diencephalon becomes chiefly the *thalamus* and *hypothalamus*, and has a pair of cuplike lateral outgrowths, the *optic vesicles*, which become the retinas of the eyes. The metencephalon gives rise to the pons and cerebellum, and the myelencephalon to the medulla oblongata. Figure 14.4 is color-coded to show which mature brain regions develop from each vesicle.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. List the three major parts of the brain and describe their locations.
2. Define *gyrus* and *sulcus*.
3. Contrast the composition and locations of gray and white matter in the brain.
4. Explain how the five secondary brain vesicles arise from the neural tube.

⁷*pros* = before, in front; *encephal* = brain

⁸*mes* = middle

⁹*rhomb* = rhombus

¹⁰*tele* = end, remote

¹¹*di* = through, between

¹²*met* = behind, beyond, distal to

¹³*myel* = spinal cord

⁵*corpus* = body; *call* = thick

⁶*cereb* = brain; *ellum* = little

14.2 Meninges, Ventricles, Cerebrospinal Fluid, and Blood Supply

Expected Learning Outcomes

When you have completed this section, you should be able to

- describe the meninges of the brain;
- describe the fluid-filled chambers in the brain;
- discuss the production, circulation, and function of the cerebrospinal fluid that fills these chambers; and
- explain the significance of the brain barrier system.

14.2a Meninges

The brain is enveloped in three membranes, the *meninges*, which lie between the nervous tissue and bone. They protect the brain and provide a structural framework for its arteries and veins. As in the spinal cord, these are the *dura mater*, *arachnoid mater*, and *pia mater* (fig. 14.5). Their histological composition is described in chapter 13 and is similar in the cranial cavity. However, the cranial dura mater consists of two layers—an outer *periosteal layer* equivalent to the periosteum of the cranial bones, and an inner *meningeal layer*. Only the meningeal layer continues into the vertebral canal, where

it forms the dural sheath around the spinal cord. The cranial dura mater is pressed closely against the cranial bone, with no intervening epidural space like the one around the spinal cord. It isn't attached to the bone, however, except in limited places: around the foramen magnum, the sella turcica, the crista galli, and the skull sutures.

In some places, the two layers of dura are separated by **dural sinuses**, spaces that collect blood that has circulated through the brain. Two major, superficial ones are the **superior sagittal sinus**, found just under the calvaria along the median line, and the **transverse sinus**, which runs horizontally from the rear of the head toward each ear. These sinuses meet like an inverted T at the back of the head and ultimately empty into the internal jugular veins of the neck. These and other sinuses of the brain are more fully described and pictured along with other cerebral blood vessels in chapter 20.

In certain places, the meningeal layer of the dura folds inward to separate major parts of the brain from each other and limit brain movements within the cranium, as when one receives a jolt to the head. There are three of these: (1) the *falx*¹⁴ *cerebri* (falks SER-eh-bry), which extends into the longitudinal cerebral fissure as a tough, crescent-shaped wall between the right and left

¹⁴*falx* = sickle

FIGURE 14.4 Primary and Secondary Vesicles of the Embryonic Brain. (a) The primary vesicles at 4 weeks. (b) The secondary vesicles at 5 weeks. (c) The fully developed brain, color-coded to relate its structures to the secondary embryonic vesicles.

cerebral hemispheres; (2) the *tentorium*¹⁵ *cerebelli* (ten-TOE-ree-um), which stretches like a roof over the posterior cranial fossa and separates the cerebellum from the overlying cerebrum; and (3) the *falx cerebelli*, a vertical partition between the right and left halves of the cerebellum on the inferior side.

The arachnoid mater and pia mater are similar to those of the spinal cord. The arachnoid mater is a transparent membrane over the brain surface, deep to the dura. A *subarachnoid space* separates it from the pia below; it is filled with cerebrospinal fluid and contains the largest blood vessels of the cerebral surface. The pia mater is a thin, delicate membrane, not usually visible without a microscope. Whereas the arachnoid meninx only overlies the sulci of the cerebral surface, the pia mater dips down into them, closely follows all the contours of the brain, and follows arteries for a short distance as they penetrate into the cerebrum.

¹⁵tentorium = tent

14.2b Ventricles and Cerebrospinal Fluid

The brain has four internal chambers called **ventricles** (fig. 14.6). The largest and most rostral ones are the two **lateral ventricles**, which form an arc shaped like a ram's horn in each cerebral hemisphere. Through a tiny pore called the **interventricular foramen**, each lateral ventricle is connected to the **third ventricle**, a narrow median space inferior to the corpus callosum. From here, a canal called the **cerebral aqueduct** passes down the core of the midbrain and leads to the **fourth ventricle**, a small triangular chamber between the pons and cerebellum. Caudally, this space narrows and forms a **central canal** that extends through the medulla oblongata into the spinal cord.

On the floor or wall of each ventricle is a spongy mass of blood capillaries called a **choroid plexus** (CO-royd), named for its histological resemblance to a fetal membrane called the chorion. *Ependyma*, a type of neuroglia that resembles a cuboidal

DEEPER INSIGHT 14.1

CLINICAL APPLICATION

Meningitis

Meningitis—inflammation of the meninges—is one of the most serious diseases of infancy and childhood. It occurs especially between 3 months and 2 years of age. Meningitis is caused by a variety of bacteria, fungi, and viruses that invade the CNS by way of the nose and throat, often following respiratory, throat, or ear infections. The pia and arachnoid mater are most often affected, and from there the infection can spread to the adjacent nervous tissue. Meningitis can cause swelling of the brain, cerebral hemorrhaging, and sometimes death within mere hours of the onset of symptoms. Signs and symptoms include high fever, stiff neck, drowsiness, intense headache, and vomiting. Meningitis is diagnosed partly by examining the cerebrospinal fluid (CSF) for bacteria and white blood cells. The CSF is obtained by lumbar puncture (described in Deeper Insight 13.1).

Death from meningitis can occur so suddenly that infants and children with a high fever should receive immediate medical attention. Freshman college students show a slightly elevated incidence of meningitis, especially those living in crowded dormitories rather than off campus.

epithelium, lines the ventricles and canals and covers the choroid plexuses. It produces cerebrospinal fluid.

Cerebrospinal fluid (CSF) is a clear, colorless liquid that fills the ventricles and canals of the CNS and bathes its external surface. It is secreted into the ventricles by the choroid plexuses and general ependymal lining, and into the subarachnoid space on the brain surface. The brain produces about 500 mL of CSF per day, but the fluid is constantly reabsorbed at the same rate and only 100 to 160 mL is normally present at one time. CSF production begins with the filtration of blood plasma through the capillaries of the brain. Ependymal cells modify the filtrate as it passes through them, so the CSF has more sodium chloride than blood plasma, but less potassium, calcium, and glucose and very little protein.

CSF continually flows through and around the CNS, driven partly by its own pressure, partly by the beating of ependymal cilia, and partly by rhythmic pulsations of the brain produced by each heartbeat. The CSF of the lateral ventricles flows through the interventricular foramina into the third ventricle, then down the cerebral aqueduct to the fourth ventricle (**fig. 14.7**). The third and fourth ventricles and their choroid plexuses add more CSF along the way.

FIGURE 14.6 Ventricles of the Brain. (a) Right lateral view. (b) Anterior view. (c) Superior view of a horizontal section of the cadaver brain, showing the lateral ventricles and some other features of the cerebrum. **APR**

c: Rebecca Gray/Don Kincaid/McGraw Hill

A small amount of CSF fills the central canal of the spinal cord, but ultimately, all of it escapes through three pores (apertures) in the fourth ventricle. These lead into the subarachnoid space on the brain and spinal cord surface. From there, CSF is reabsorbed by **arachnoid granulations**, extensions of the arachnoid meninx shaped like little sprigs of cauliflower, protruding through the dura mater into the superior sagittal sinus. CSF penetrates the walls of the granulations and mixes with blood in the sinus.

Cerebrospinal fluid serves three purposes:

1. **Buoyancy.** Because the brain and CSF are similar in density, the brain neither sinks nor floats in the CSF. It hangs from delicate strands of the arachnoid meninx. A human brain removed from the body has a dead weight of about 1,250 g, but when suspended in CSF, its effective weight is only about 50 g. By analogy, consider how much easier it is to lift another person when you're immersed in a lake than it is on land. This buoyancy allows the brain
2. **Protection.** CSF also protects the brain from striking the cranium when the head is jolted. If the jolt is severe, however, the brain still may strike the inside of the cranium or suffer shearing injury from contact with the angular surfaces of the cranial floor. This is one of the common findings in child abuse (shaken child syndrome) and in concussions and other *traumatic brain injury (TBI)* from falls, auto accidents, boxing, football, and the like.
3. **Chemical stability.** CSF rinses metabolic wastes from the nervous tissue and regulates its chemical environment. Slight changes in CSF composition can cause malfunctions of the nervous system. For example, a high glycine concentration disrupts the control of body temperature and blood pressure, and a high pH causes dizziness and fainting.

FIGURE 14.7 The Flow of Cerebrospinal Fluid.

CSF is far more, however, than simply a passively flowing rinse and cushion for the brain. It contains numerous hormones, growth factors, and other neuroactive chemicals that influence embryonic brain and spinal cord development, sleep, appetite, posture, locomotion, and other functions. Certain specialized neurons project into the CSF and seem to communicate information about its composition to the deeper brain tissue. The chemical composition of CSF and its full range of physiological effects are only beginning to be understood. Further aspects of CSF function are discussed with the glymphatic system of the brain in chapter 21.

14.2c Blood Supply and the Brain Barrier System

The blood vessels that serve the brain are detailed in chapter 20. The brain constitutes only 2% of the adult body weight, yet it receives 15% of the blood flow (about 750 mL/min.) and consumes 20% of its oxygen and glucose. Because neurons have such a high demand for ATP, and therefore glucose and oxygen, the constancy of blood supply is especially critical to the nervous system. A mere 10-second interruption in blood flow causes loss of consciousness; an interruption of 1 to 2 minutes significantly impairs neural function; and 4 minutes without blood usually causes irreversible brain damage (see Deeper Insight 14.2). For more on cerebral blood flow, see section 20.5a.

Despite its critical importance to the brain, blood is also a source of antibodies, macrophages, bacterial toxins, and other potentially harmful agents. Damaged brain tissue is essentially irreplaceable, and the brain therefore must be well protected. Consequently, there is a **brain barrier system (BBS)** that strictly regulates what can get from the bloodstream into the tissue fluid of the brain.

There are two potential points of entry that must be guarded: the blood capillaries throughout the brain tissue and the capillaries of the choroid plexuses. At the former site, the brain is well protected by the **blood–brain barrier**, which consists of tight junctions between the endothelial cells that form the capillary walls. In the developing brain, astrocytes reach out and contact the capillaries with their perivascular feet, stimulating the endothelial cells to form tight junctions that completely seal off the gaps between them. This ensures that anything leaving the blood must pass through the cells and not between them. The endothelial cells are more selective than gaps between them would be, and can exclude harmful substances from the brain tissue while allowing necessary ones to pass through. At the choroid plexuses, the brain is protected by a similar **blood–CSF barrier** formed by tight junctions between the ependymal cells. Tight junctions are absent from ependymal cells elsewhere because it's important to allow exchanges between the brain tissue and CSF. That is, there is no brain–CSF barrier.

The BBS is highly permeable to water, glucose, and lipid-soluble substances such as oxygen, carbon dioxide, alcohol, caffeine, nicotine, and anesthetics. It is slightly permeable to sodium, potassium, chloride, and the waste products urea and creatinine. While the BBS is an important protective device, it is an obstacle to the delivery of medications such as antibiotics and cancer drugs, and thus complicates the treatment of brain diseases.

Trauma and inflammation sometimes damage the BBS and allow pathogens to enter the brain tissue. Furthermore, there are places called **circumventricular organs (CVOs)** in the third and fourth ventricles where the barrier is absent and the blood has direct access to brain neurons. These enable the brain to monitor and respond to fluctuations in blood glucose, pH, osmolarity, and other variables. Unfortunately, CVOs also afford a route of invasion by the human immunodeficiency virus (HIV).

DEEPER INSIGHT 14.2

CLINICAL APPLICATION

Stroke

A **stroke**, or **cerebral vascular accident (CVA)**, is the sudden death of brain tissue resulting from an abrupt interruption of its blood supply. There are two kinds of stroke distinguished by cause: a *hemorrhagic stroke* resulting from the rupture of a cerebral or subarachnoid blood vessel, and more common, an *ischemic stroke* (iss-KEE-mic) resulting from the obstruction of a blood vessel, usually by a blood clot (thrombosis) or lipid deposit (atherosclerosis). Except in unusual times such as the COVID-19 pandemic starting in 2019, stroke is the second greatest cause of death after coronary artery disease; about one-half of those who have a stroke live less than 1 year longer. Stroke can occur at any age, but about two-thirds occur in people over 65 years old.

Aside from age, risk factors for stroke include hypertension; high blood cholesterol; obesity; diabetes mellitus; and such lifestyle choices as inadequate physical activity, overuse of alcohol, smoking, and using drugs such as amphetamines and cocaine. The risk of stroke can be reduced with statin drugs (to lower cholesterol level); antihypertensive drugs (to control blood pressure); and other lifestyle, medical, and surgical methods. Daily low-dose aspirin hasn't proven helpful for *primary prevention* of a first stroke, but may be beneficial

for *secondary prevention* of recurrence in those who have had a previous stroke.

The signs and symptoms of a stroke depend on the function of the tissues downstream from the hemorrhage or obstruction, where neuron death occurs. They can include paralysis (usually on the side of the body opposite from a cerebral stroke); inability to stick the tongue out and move it left and right on command; blindness, defects in the visual field, or other loss of sensation; aphasia (loss of articulate speech); or cognitive deficits (dysfunctions in awareness, memory, or reason). Similar symptoms lasting less than 24 hours are called *transient ischemic attack (TIA)*, colloquially called a “mini-stroke.” A TIA can foreshadow a true stroke later.

To be prepared to accurately recognize a stroke in another person and get quick help, think of the acronym **FAST**: **F**acial weakness (sagging or drooping on one side of the face), **A**rm drift (inability to prevent one arm from drifting down when asked to hold both arms above the head), **S**peech difficulty, and **T**ime to call emergency services. Irreversible brain damage (neuron death) occurs after about 3 hours and is therefore preventable with prompt emergency treatment—as stressed by the slogan, Time is brain!

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

5. Name the three meninges from superficial to deep. How does the dura mater of the brain differ from that of the spinal cord?
6. Describe three functions of the cerebrospinal fluid.
7. Where does the CSF originate and what route does it take through and around the CNS?
8. Name the two components of the brain barrier system and explain the importance of this system.

14.3 The Hindbrain and Midbrain

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. list the components of the hindbrain and midbrain and their functions; and
- b. describe the location and functions of the reticular formation.

The study of the brain in the following pages will be organized around the five secondary vesicles of the embryonic brain and their mature derivatives. We will proceed in a caudal to rostral direction, beginning with the brainstem and its relatively simple functions and progressing to the forebrain, the seat of such complex functions as thought, memory, and emotion. Recall that the brainstem consists of the medulla oblongata, pons, and midbrain.

14.3a The Medulla Oblongata

As noted earlier, the embryonic hindbrain differentiates into two subdivisions: the myelencephalon and metencephalon (see fig. 14.4). The myelencephalon becomes just one adult structure, the **medulla oblongata** (meh-DULL-uh OB-long-GAH-ta).

The medulla (fig. 14.8; also see fig. 14.2) begins at the foramen magnum of the skull and extends for about 3 cm rostrally, ending at a transverse groove between the medulla and pons. It looks superficially like an extension of the spinal cord, but slightly wider. Significant differences are apparent, however, on closer inspection of its gross and microscopic anatomy. Externally, the anterior surface features a pair of ridges called the **pyramids**. Resembling side-by-side baseball bats, these are wider at the rostral end, taper caudally, and are separated by a longitudinal groove, the **anterior median fissure**, continuous with that of the spinal cord. From the posterolateral view, one can see a prominent bulge called the **olive** lateral to each pyramid, and a pair of ridges, the **gracile** and **cuneate fasciculi**, which are continuations of those of the spinal cord.

All nerve fibers connecting the brain to the spinal cord pass through the medulla. As we saw in the cord, some of these are ascending (sensory) and some are descending (motor) fibers.

The ascending fibers include first-order sensory fibers of the gracile and cuneate fasciculi, which end in the *gracile* and *cuneate nuclei* seen in figure 14.9c. Here, they synapse with second-order neurons whose fibers decussate and form the ribbonlike *medial lemniscus*¹⁶ on each side. These second-order fibers rise to the thalamus, synapsing there with third-order neurons whose fibers complete the path to the cerebral cortex (compare fig. 13.6a).

The largest group of descending fibers is the pair of **corticospinal tracts** filling the pyramids on the anterior surface. These carry motor signals from the cerebral cortex on the way to the spinal cord, ultimately to stimulate the skeletal muscles. Any time you carry out a body movement below the neck, the signals en route to your muscles pass through here. About 90% of these fibers cross over at the *pyramidal decussation*, an externally visible point near the caudal end of the pyramids (fig. 14.8a). As a result, muscles below the neck are controlled by the contralateral side of the brain. A smaller *tectospinal tract* controls the neck muscles.

The medulla contains nuclei involved in a multitude of fundamental sensory and motor functions. The former include the senses of hearing, equilibrium, touch, pressure, temperature, taste, and pain; the latter include chewing, salivation, swallowing, gagging, vomiting, respiration, speech, coughing, sneezing, sweating, cardiovascular and gastrointestinal control, and head, neck, and shoulder movements. Signals for these functions enter and leave the medulla not only by way of the spinal cord, but also by four pairs of cranial nerves that begin or end here: cranial nerves VIII (in part), IX, X, and XII. At the level of the section in figure 14.9c, we see the origins of two of them, the vagus (X) and hypoglossal (XII). The names and functions of these nerves are detailed in section 14.6c.

Another feature seen in cross section is the wavy **inferior olivary nucleus**, a major relay center for signals going from many levels of the brain and spinal cord to the cerebellum. The *reticular formation*, detailed later, is a loose network of nuclei extending throughout the medulla, pons, and midbrain. In the medulla, it includes a **cardiac center**, which regulates the rate and force of the heartbeat; a **vasomotor center**, which regulates blood pressure and flow by dilating and constricting blood vessels; two **respiratory centers**, which regulate the rhythm and depth of breathing; and other nuclei involved in the aforementioned motor functions.

14.3b The Pons

The metencephalon develops into the pons and cerebellum. We will return to the cerebellum after finishing the brainstem. The **pons**¹⁷ (fig. 14.9b) measures about 2.5 cm long. Most of it appears as a broad anterior bulge rostral to the medulla. Posteriorly, it consists mainly of two pairs of thick stalks called *cerebellar peduncles*, the cut edges in the upper half of the figure. They connect the cerebellum to the pons and midbrain and will be discussed with the cerebellum.

In cross section, the pons exhibits continuations of the previously mentioned reticular formation, medial lemniscus,

¹⁶*lemn* = ribbon; *iscus* = little

¹⁷*pons* = bridge

FIGURE 14.8 The Brainstem and Diencephalon. (a) Anterior view. (b) Posterolateral view. Color-coded to match the embryonic origins in figure 14.4. The boundary between the middle and inferior cerebellar peduncles is indistinct. **APR**

tectospinal tract, and other spinal tracts. The anterior half of the pons (lower half of the figure) is dominated by tracts of white matter, including transverse fascicles that cross between left and right and connect the two hemispheres of the cerebellum, and longitudinal fascicles that carry sensory and motor signals up and down the brainstem.

Cranial nerves V to VIII begin or end in the pons, although we see only the trigeminal nerve (V) at the level illustrated.

The other three emerge from the groove between the pons and medulla. The functions of these four nerves, detailed in table 14.1, include sensory roles in hearing, equilibrium, and taste; facial sensations such as touch and pain; and motor roles in eye movement, facial expressions, chewing, swallowing, urination, and the secretion of saliva and tears. The reticular formation in the pons contains additional nuclei concerned with sleep, respiration, and posture.

FIGURE 14.9 Cross Sections of the Brainstem. The level of each section is shown in the figure on the right. (a) The midbrain, cut obliquely to pass through the superior colliculi. (b) The pons. The straight edges indicate cut edges of the peduncles where the cerebellum was removed. (c) The medulla oblongata. **APR**

? Trace the route taken through all three of these figures by fibers from the gracile and cuneate fasciculi described in section 13.1e.

14.3c The Midbrain

The mesencephalon becomes just one mature brain structure, the **midbrain** (**fig. 14.9a**)—a short segment of brainstem that connects the hindbrain and forebrain (see **figs. 14.2, 14.8**). It contains the cerebral aqueduct, continuations of the medial lemniscus and reticular formation, and the motor nuclei of two cranial nerves that control eye movements: cranial nerves III (oculomotor) and IV (trochlear). Only the first of these is seen at the level illustrated. (The *medial geniculate nucleus* seen in this figure is not part of the midbrain, but a part of the thalamus that happens to lie in the plane of this section.)

The part of the midbrain posterior to the cerebral aqueduct is a rooflike **tectum**.¹⁸ It exhibits four bulges. The upper (rostral) pair, called the **superior colliculi**¹⁹ (col-LIC-you-lye), control the *extrinsic muscles* of the eyes, enabling us to direct our gaze at a target, track moving objects, and turn the eyes and head in response to a visual stimulus (for example, to look at something that you catch sight of in your peripheral vision). Between the superior colliculi and thalamus are other visual control centers, the **pretectal nuclei**, that control pupillary diameter and focusing of the lens. The lower (caudal) pair, called the **inferior colliculi**, receives signals from the inner ear and relays them to other parts of the brain, especially the thalamus. These colliculi are sensitive to the time delays between sounds heard by the two ears and thus aid in locating the source of a sound in space. They also process fluctuations in pitch, which is important for such purposes as understanding another person's speech. They also mediate the reflexive turning of the head in response to a sound and one's tendency to jump when startled by a sudden noise.

Anterior to the cerebral aqueduct, the midbrain consists mainly of the **cerebral peduncles**—two stalks that anchor the cerebrum to the brainstem. Each peduncle has three main components: tegmentum, substantia nigra, and cerebral crus. The **tegmentum**²⁰ is dominated by the **red nucleus**, named for a pink color imparted by its high density of blood vessels. Fibers from the red nucleus form the *rubrospinal tract* in most mammals, but in humans its connections go mainly to and from the cerebellum, with which it collaborates in fine motor control. The **substantia nigra**²¹ (sub-STAN-she-uh NY-gruh) is a dark gray to black nucleus pigmented with melanin. It is a motor center that relays inhibitory signals to the thalamus and basal nuclei (both of which are discussed later), suppressing unwanted body movement. Degeneration of the neurons in the substantia nigra leads to the muscle tremors of Parkinson disease (see Deeper Insight 12.4). The **cerebral crus** (plural, *crura*) is a bundle of nerve fibers that connect the cerebrum to the pons and carry the corticospinal nerve tracts.

The cerebral aqueduct is encircled by the **central (periaqueductal) gray substance**. This is involved with the reticular formation in controlling awareness of pain, as further discussed in chapter 16.

FIGURE 14.10 The Reticular Formation. The formation consists of over 100 nuclei scattered throughout the brainstem. Magenta ascending arrows indicate routes of input to the reticular formation; blue arrows indicate the radiating relay of signals from the thalamus to the cerebral cortex; and green descending arrows indicate output from the reticular formation to the spinal cord.

? Locate components of the reticular formation in all three parts of figure 14.9.

▶▶▶ APPLY WHAT YOU KNOW

Why are the inferior colliculi shown in figure 14.8b but not in figure 14.9a? How are these two figures related?

14.3d The Reticular Formation

The **reticular**²² **formation** is a loosely organized web of gray matter that runs vertically through all levels of the brainstem and the upper spinal cord, appearing at all three levels of figure 14.9. It occupies much of the space between the white fiber tracts and the more anatomically distinct brainstem nuclei, and has connections with many areas of the cerebrum (**fig. 14.10**). It consists of more than 100 small nuclei defined less by anatomical boundaries than

¹⁸ *tectum* = roof, cover

¹⁹ *colli* = hill; *cul* = little

²⁰ *tegmen* = cover

²¹ *substantia* = substance; *nigra* = black

²² *ret* = network; *icul* = little

by their use of different neurotransmitters. The functions of these nuclei include the following:

- **Somatic motor control.** Some motor neurons of the cerebral cortex send their axons to reticular formation nuclei, which then give rise to the *reticulospinal tracts* that descend the spinal cord. These tracts adjust muscle tension to maintain tone, balance, and posture, especially during body movements. The reticular formation also relays signals from the eyes and ears to the cerebellum so the cerebellum can integrate visual, auditory, and vestibular (balance and motion) stimuli into its role in motor coordination. Other motor nuclei include *gaze centers*, which enable the eyes to track and fixate objects, and *central pattern generators*—neural pools that produce rhythmic signals to the muscles of breathing and swallowing.
- **Cardiovascular control.** The reticular formation includes the previously mentioned cardiac and vasomotor centers of the medulla oblongata.
- **Pain modulation.** The reticular formation is one route by which pain signals from the lower body reach the cerebral cortex. It is also the origin of the *descending analgesic pathways* mentioned in the description of the reticulospinal tracts in chapter 13. Under certain circumstances, the nerve fibers in these pathways act in the spinal cord to deaden one's awareness of pain.
- **Sleep and consciousness.** The reticular formation has projections to the thalamus and cerebral cortex that allow it some control over what sensory signals reach the cerebrum and come to our conscious attention. It plays a central role in states of consciousness such as alertness and sleep. Injury to the reticular formation can result in irreversible coma.
- **Habituation.** This is a process in which the brain learns to ignore repetitive, inconsequential stimuli while remaining sensitive to others. In a noisy city, for example, a person can sleep through traffic sounds but wake promptly to the sound of an alarm clock or a crying baby. Reticular formation nuclei that modulate activity of the cerebral cortex are called the *reticular activating system* or *extrathalamic cortical modulatory system*.

14.3e The Cerebellum

The cerebellum is the largest part of the hindbrain and second-largest part of the brain as a whole (**fig. 14.11**). It consists of right and left **cerebellar hemispheres** connected by a narrow worm-like bridge called the **vermis**.²³ Each hemisphere exhibits slender, transverse, parallel folds called **folia**²⁴ separated by shallow sulci. The cerebellum has a surface cortex of gray matter and a deeper layer of white matter. In a sagittal section, the white matter exhibits a branching, fernlike pattern called the **arbor vitae**.²⁵ Each hemisphere has four masses of gray matter called **deep nuclei** embedded in the white matter. All input to the cerebellum goes to the cortex and all of its output comes from the deep nuclei.

Although the cerebellum is only about 10% of the mass of the brain, it has about 60% as much surface area as the cerebral cortex and it contains more than half of all brain neurons. Its tiny, densely spaced **granule cells** are the most abundant type of neuron in the entire brain. Its most distinctive neurons, however, are the unusually large, globose **Purkinje**²⁶ **cells** (pur-KIN-jee). These have a tremendous profusion of dendrites compressed into a single plane like a flat tree (see **fig. 12.5**). The Purkinje cells are arranged in a single file, with these thick dendritic planes parallel to each other like books on a shelf. Their axons travel to the deep nuclei, where they synapse on output neurons whose axons lead to the brainstem.

The cerebellum is connected to the brainstem by three pairs of stalks called **cerebellar peduncles**²⁷ (peh-DUN-culs): a pair of *inferior peduncles* connected to the medulla oblongata, a pair of *middle peduncles* to the pons, and a pair of *superior peduncles* to the midbrain (see **fig. 14.8b**). These consist of thick bundles of nerve fibers that carry signals to and from the cerebellum. Connections between the cerebellum and brainstem are complex, but overlooking some exceptions, we can draw a few generalizations. Most spinal input enters the cerebellum by way of the inferior peduncles; most input from the rest of the brain enters by way of the middle peduncles; and cerebellar output travels mainly by way of the superior peduncles.

The function of the cerebellum was unknown in the 1950s. By the 1970s, it had come to be regarded as a center for monitoring muscle contractions and aiding in motor coordination. People with cerebellar lesions exhibit serious deficits in coordination and locomotor ability; more will be said later in this chapter about the role of the cerebellum in movement (see **section 14.5g**). But cerebellar lesions also affect several sensory, linguistic, emotional, and other nonmotor functions. Recent studies by positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) (both described in **Deeper Insight 1.5**), and behavioral studies of people with cerebellar lesions, have created a much more expansive view of cerebellar function. It appears that its general role is the evaluation of certain kinds of sensory input, and monitoring muscle movement is only part of its broader function.

The cerebellum is highly active when, for example, a person explores objects with the fingertips to compare their textures without looking at them. (Tactile nerve fibers from a rat's snout and a cat's forepaws also feed into the cerebellum.) Some spatial perception also resides here. The cerebellum is much more active when a person is required to solve a pegboard puzzle than when moving pegs randomly around the same puzzle board. Some people with cerebellar lesions have difficulty identifying different views of a three-dimensional object as belonging to the same object.

The cerebellum is also a timekeeper. PET scans show increased cerebellar activity when a person is required to judge the elapsed time between two stimuli. People with cerebellar lesions have difficulty with rhythmic finger-tapping tasks and other tests of

²³verm = worm

²⁴foli = leaf

²⁵arbor = tree; vitae = of life

(b) Superior view. **APR**

temporal judgment. An important aspect of cerebellar timekeeping is the ability to predict where a moving object will be in the next second or so. You can imagine the importance of this to a predator chasing its prey, to a tennis player, or in driving a car in heavy traffic. The cerebellum also helps to predict how much the eyes must move in order to compensate for head movements and remain fixed on an object.

Even hearing has some newly discovered and surprising cerebellar components. Cerebellar lesions impair a person's ability to judge differences in pitch between two tones and to distinguish between similar-sounding words such as *rabbit* and *rapid*. Language output also involves the cerebellum. If a person is given a noun such as *apple* and told to think of a related verb such as *eat*, the cerebellum shows higher PET activity than if the person is told merely to repeat the word *apple*.

People with cerebellar lesions also have difficulty planning and scheduling tasks. They tend to overreact emotionally and have difficulty with impulse control. Many children with

attention-deficit/hyperactivity disorder (ADHD) have abnormally small cerebellums.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

9. List several visceral functions controlled by nuclei of the medulla oblongata. What general function would be lost if the pyramids of the medulla were severed?
10. List several sensory and motor functions of the pons.
11. What functions are served by the superior and inferior colliculi? To what portion of the brainstem do they belong?
12. Where is the reticular formation found? Define *reticular formation* in a single sentence.
13. List several functions of the cerebellum.

14.4 The Forebrain

Expected Learning Outcomes

When you have completed this section, you should be able to

- name the three major components of the diencephalon and describe their locations and functions;
- identify the five lobes of the cerebrum and their functions;
- describe the three types of tracts in the cerebral white matter;
- describe the distinctive cell types and histological arrangement of the cerebral cortex; and
- describe the location and functions of the basal nuclei and limbic system.

The forebrain consists of the diencephalon and telencephalon. The diencephalon encloses the third ventricle and is immediately rostral to the brainstem. The telencephalon develops chiefly into the cerebrum.

14.4a The Diencephalon

Three structures arise from the embryonic diencephalon: the *thalamus*, *hypothalamus*, and *epithalamus*.

The Thalamus

Each side of the brain has a **thalamus**,²⁸ an ovoid mass perched at the superior end of the brainstem beneath the cerebral hemisphere (see figs. 14.6c, 14.8, 14.17). The two thalami form about four-fifths of the diencephalon. Laterally, they protrude into the lateral ventricles. Medially, they protrude into the third ventricle and are joined to each other by a narrow bridge, the *interthalamic adhesion*, in about 70% of people.

The thalamus consists of at least 23 nuclei, most of which fall into five groups: anterior, posterior, medial, lateral, and ventral. These groups and their functions are shown in **figure 14.12a**.

Broadly speaking, the thalamus is the “gateway to the cerebral cortex.” Nearly all input to the cerebrum passes by way of synapses in the thalamic nuclei, including signals for taste, hearing, equilibrium, vision, and such general senses as touch, pain, pressure, heat, and cold. The thalamic nuclei process this information, screen out much of it, and relay a small portion of it to appropriate areas of the cerebral cortex.

The thalamus also serves in motor control by relaying signals from the cerebellum to the cerebrum and providing feedback loops between the cerebral cortex and the *basal nuclei* (deep cerebral motor centers). Finally, the thalamus is involved in the memory and emotional functions of the *limbic system*, a complex of structures that include some cerebral cortex of the temporal and frontal

lobes and some of the anterior thalamic nuclei. The role of the thalamus in motor and sensory circuits is further discussed later in this chapter and chapter 16.

The Hypothalamus

The **hypothalamus** (see fig. 14.2) forms the floor and part of the walls of the third ventricle. It extends anteriorly to the *optic chiasm* (ky-AZ-um), where the optic nerves meet, and posteriorly to a pair of humps called the **mammillary**²⁹ **bodies**. The pituitary gland is attached to the hypothalamus by a stalk (*infundibulum*) between the optic chiasm and mammillary bodies.

The hypothalamus is the major control center of the endocrine and autonomic nervous systems. It plays an essential role in the homeostatic regulation of nearly all organs of the body. Its nuclei include centers concerned with a wide variety of visceral, emotional, and even behavioral functions (**fig. 14.12b**):

- **Hormone secretion.** The hypothalamus secretes hormones that control the anterior pituitary gland, thereby regulating growth, metabolism, reproduction, and stress responses. It also produces hormones that are stored in the posterior pituitary gland, concerned with labor contractions, lactation, and water conservation. These relationships are explored especially in chapter 17.
- **Autonomic effects.** The hypothalamus is a major integrating center for the autonomic nervous system. It sends descending fibers to lower brainstem nuclei that influence heart rate, blood pressure, gastrointestinal secretion and motility, and pupillary diameter, among other functions.
- **Thermoregulation.** The *hypothalamic thermostat* consists of a collection of neurons, concentrated especially in the preoptic nucleus, that monitor body temperature. When the temperature deviates too much from its set point, this center activates mechanisms for lowering or raising the body temperature.
- **Food and water intake.** The hypothalamus regulates sensations of hunger and satiety. The *arcuate nucleus*, in particular, contains receptors for hormones that increase hunger and energy expenditure, other hormones that reduce both, and hormones that exert long-term control over body mass. Hypothalamic neurons called *osmoreceptors* monitor blood osmolarity and stimulate water-seeking and drinking behavior when the body is dehydrated. Dehydration also stimulates the hypothalamus to produce *antidiuretic hormone*, which conserves water by reducing urine output.
- **Sleep and circadian rhythms.** The caudal part of the hypothalamus is part of the reticular formation. It contains nuclei that regulate the rhythm of sleep and waking. Superior to the optic chiasm, the hypothalamus contains a *suprachiasmatic nucleus* that controls our 24-hour (circadian) rhythm of activity.

²⁸thalamus = chamber, inner room

²⁹mammill = nipple

Thalamic nuclei	
Anterior group	Part of limbic system; memory and emotion
Medial group	Emotional output to prefrontal cortex; awareness of emotions
Ventral group	Somatosensory output to postcentral gyrus; signals from cerebellum and basal nuclei to motor areas of cortex
Lateral group	Somatosensory output to association areas of cortex; contributes to emotional function of limbic system
Posterior group	Relay of visual signals to occipital lobe (via lateral geniculate nucleus) and auditory signals to temporal lobe (via medial geniculate nucleus)
Hypothalamic nuclei	
Anterior nucleus	Thirst center; thermoregulation
Arcuate nucleus	Regulates appetite; secretes releasing hormones that regulate anterior pituitary
Dorsomedial nucleus	Rage and other emotions; sleep regulation
Mammillary body	Relay between limbic system and thalamus; involved in long-term memory
Paraventricular nucleus	Produces oxytocin (involved in childbirth, lactation, orgasm); controls posterior pituitary
Posterior nucleus	Functions with central gray substance of midbrain in emotional, cardiovascular, and pain control
Preoptic nucleus	Hormonal control of reproductive functions; monitors body temperature
Suprachiasmatic nucleus	Biological clock; regulates sleep, other circadian rhythms, and female reproductive cycle
Supraoptic nucleus	Produces antidiuretic hormone (involved in water balance); controls posterior pituitary
Ventromedial nucleus	Plays roles in glucose and lipid metabolism, appetite, thermoregulation, sexual behavior, and emotion

FIGURE 14.12 The Diencephalon. (a) Nuclei of the thalamus. (b) Nuclei of the hypothalamus. Only some of the nuclei of the thalamus and hypothalamus are shown, and some of their functions are listed. These lists are by no means complete. **APR**

- **Memory.** Each mammillary body contains three or four nuclei that serve mainly to relay signals from the hippocampus, an important memory center of the brain, to the thalamus. Thus, they are important in memory, and lesions to the mammillary nuclei cause memory deficits. (For a more complete discussion, see section 14.5d.)
- **Emotional behavior and sexual response.** Hypothalamic centers are involved in a variety of emotional responses

including anger, aggression, fear, pleasure, and contentment; and in sexual drive, copulation, and orgasm. The hypothalamus may even influence sexual orientation and attraction. One nucleus, the *interstitial nucleus 3 of the anterior hypothalamus (INAH-3)*, about the size of a grain of sand in heterosexual males, is measurably smaller in women and gay males. Whether this is by cause or effect of sexual orientation, or merely correlated with it, remains uncertain.

The Epithalamus

The **epithalamus** is a small mass composed mainly of the **pineal gland** (an endocrine gland discussed in chapter 17), the **habenula**³⁰ (a relay from the limbic system to the midbrain), and a thin roof over the third ventricle (see fig. 14.2a).

14.4b The Cerebrum

The embryonic telencephalon becomes the cerebrum, the largest and most conspicuous part of the human brain. Your cerebrum enables you to turn or scroll these pages, read and comprehend the words, remember ideas, talk about them with your peers, and take an examination. It is the seat of voluntary motor control and our most distinctly human mental processes. It is the most complex and challenging frontier of neurobiology.

Gross Anatomy

The cerebrum so dwarfs and conceals the other structures that people often think of “cerebrum” and “brain” as synonymous. Its major anatomical landmarks were described at the beginning of this chapter and should be reviewed if necessary (see figs. 14.1 and 14.2); most important are the two *cerebral hemispheres*, separated by the *longitudinal cerebral fissure* but connected by a prominent fiber tract, the *corpus callosum*; and the conspicuous wrinkles, or *gyri*, of each hemisphere, separated by grooves called *sulci*. The folding

of the cerebral surface into gyri allows a greater amount of cortex to fit in the cranial cavity. The gyri give the cerebrum a surface area of about 2,500 cm². If the cerebrum were smooth-surfaced, it would have only one-third as much area and proportionately less information-processing capability. This extensive folding is one of the greatest differences between the human brain and the less convoluted brains of most other mammals.

Some gyri have consistent and predictable anatomy, while others vary from brain to brain and even from the right hemisphere to the left in the same person. Certain unusually prominent sulci divide each hemisphere into five anatomically and functionally distinct lobes, as follows. The first four are visible superficially and are named for the cranial bones overlying them; the fifth lobe (*insula*) is not visible from the surface.

It is difficult to summarize the functions of the cerebral lobes in any simple way; many functions such as vision, memory, speech, and emotion are distributed over multiple lobes, and different lobes contribute only part of the overall function. With that caveat, **figure 14.13** and the following list survey the anatomical distribution of many key cerebral functions.

1. The **frontal lobe** lies immediately behind the frontal bone, superior to the eyes. From the forehead, it extends caudally to a wavy vertical groove, the **central sulcus**. It is the seat of our conscious, abstract thought; explicit or declarative memory (see section 12.6e); cognitive and emotional processes such as mood, motivation, foresight, planning, decision making, emotional control, and judging socially

³⁰*haben* = strap, rein; *ula* = little

FIGURE 14.13 The Five Lobes of the Cerebrum and Some of Their Key Functions. The frontal and temporal lobes are retracted slightly to reveal the insula. The lists of functions are by no means exhaustive, but help to anatomically locate key functions discussed in this chapter. **APR**

- appropriate behavior; and in speech production and other voluntary control of nearly all the body's skeletal muscles.
2. The **parietal lobe** forms the uppermost part of the brain and underlies the parietal bone. Starting at the central sulcus, it extends caudally to the **parieto-occipital sulcus**, visible on the medial surface of each hemisphere (see fig. 14.2). It is concerned with taste, somatic sensation (such as touch, heat, and pain), and visual processing; multisensory integration such as correlating sights and sounds to holistically comprehend our sensory world; spatial perception and awareness of body orientation; language processing; and numerical awareness (a sense of the quantity of things we see before us).
 3. The **occipital lobe** is at the rear of the head, caudal to the parieto-occipital sulcus and underlying the occipital bone. It is the principal visual center of the brain, where we first become aware of visual stimuli and process them to identify what we see.

4. The **temporal lobe** is a lateral, horizontal lobe deep to the temporal bone, separated from the frontal and parietal lobes above it by a deep **lateral sulcus**. It is concerned with hearing; smell; emotion; learning; language comprehension and memory of the grammar and vocabulary of the languages we speak; memory consolidation (formation of new long-term memories); and storage of verbal, visual, and auditory memories.
5. The **insula**³¹ is a small mass of cortex deep to the lateral sulcus, made visible only by retracting or cutting away some of the overlying cerebrum (see figs. 14.6c and 14.17). It plays roles in taste; pain; visceral sensation; consciousness; emotional responses and empathy (sympathetic awareness of the feelings of others); and cardiovascular homeostasis (such as heart rate and blood pressure responses to exercise).

³¹insula = island

FIGURE 14.14 Tracts of Cerebral White Matter. (a) Sagittal section showing association and projection tracts. (b) Frontal section showing commissural and projection tracts.

? What route can commissural tracts take between the right and left cerebral hemispheres other than the one shown here?

The Cerebral White Matter

Most of the volume of the cerebrum is white matter. This is composed of neuroglia and myelinated nerve fibers that transmit signals from one region of the cerebrum to another and between the cerebrum and lower brain centers. Heavy myelination of the white matter gives it a bright white, opalescent appearance in contrast to the duller gray matter (see fig. 14.17). These fibers form bundles, or *tracts*, of three kinds (fig. 14.14; see also chapter opener photo):

1. **Projection tracts** extend vertically between higher and lower brain and spinal cord centers. They carry information between the cerebrum and the rest of the body. The corticospinal tracts, for example, carry motor signals from the cerebrum to the brainstem and spinal cord. Other projection tracts carry signals upward to the cerebral cortex. The latter tracts form a broad, dense sheet called the *internal capsule* between the thalamus and basal nuclei (described shortly), then radiate in a diverging, fanlike array (the *corona radiata*³²) to specific areas of the cortex.
2. **Commissural tracts** cross from one cerebral hemisphere to the other through bridges called **commissures** (COM-i-h-shurs). The great majority of commissural tracts pass through the large corpus callosum (see fig. 14.2). A few pass through the much smaller **anterior** and **posterior commissures**. Commissural tracts enable the two sides of the cerebrum to communicate with each other.
3. **Association tracts** connect different regions within the same cerebral hemisphere. *Long association fibers* connect different lobes of a hemisphere to each other, such as connecting the occipital lobe to the temporal lobe. *Short association fibers* connect different gyri within a single lobe. Among

their roles, association tracts link perceptual and memory centers of the brain; for example, they enable you to see a rose, name it, and imagine its scent.

The Cerebral Cortex

Neural integration is carried out in the gray matter of the cerebrum, which is found in three places: the cerebral cortex, basal nuclei, and limbic system. We begin with the **cerebral cortex**,³³ a layer covering the surface of the hemispheres (see fig. 14.6c). Even though it is only 2 to 3 mm thick, the cortex constitutes about 40% of the mass of the brain and contains 14 to 16 billion neurons. It possesses two principal types of neurons (fig. 14.15) called *stellate cells* and *pyramidal cells*. **Stellate cells** have spheroidal cell bodies with short axons and dendrites projecting in all directions. They are concerned largely with receiving sensory input and processing information on a local level. **Pyramidal cells** are tall and conical. Their apex points toward the brain surface and has a thick dendrite with many branches and small, knobby *dendritic spines* (see fig. 12.5a and the photo on the opening page of chapter 12). The base gives rise to lateral dendrites and an axon that passes into the white matter below. Pyramidal cells include the output neurons of the cerebrum—the only cerebral neurons whose fibers leave the cortex and connect with other parts of the CNS. Pyramidal cell axons have collaterals that synapse with other neurons in the cortex or in deeper regions of the brain.

About 90% of the human cerebral cortex is a six-layered tissue called **neocortex**³⁴ because of its relatively recent evolutionary origin. Although vertebrate animals have existed for about 600 million years, the neocortex didn't develop significantly until about 60 million years ago, when there was a sharp increase in the diversity of

³²*corona* = crown; *radiata* = radiating

³³*cortex* = bark, rind

³⁴*neo* = new

DEEPER INSIGHT 14.3 CLINICAL APPLICATION

Tracking the Tracts of White Matter

This chapter's opening photo was made with a relatively new application of magnetic resonance imaging (MRI) called *diffusion tensor imaging (DTI)*. DTI is a method of detecting the diffusion of water molecules to trace parallel bundles of myelinated nerve fibers in the white matter of the CNS. In most places, water diffusion is random and generates no useful signal. The parallel paths of nerve fibers and the insulating effect of their myelin sheaths, however, give a directionality to diffusion, since more water diffuses along the nerve fibers than across them. The computer color-codes the vectors of diffusion to display tracts passing between the left and right brain in red, anterior–posterior tracts in green, and superior–inferior tracts in blue.

The mapping of fiber tracts by DTI is called *tractography*. The most often mapped tract has been the *corticospinal tract*, the main output pathway for cerebral control of the muscles. The tract of second-greatest interest is called the *arcuate fasciculus*, which connects the Wernicke and Broca speech areas (see section 14.5h). The ultimate aim of cerebral tractography is to determine the brain's *connectome*, a complete map of the physical connections (circuitry) between brain regions.

DTI dates to the 1990s but has only more recently gained application to living patients, making it a highly sensitive imaging method for neuropathology. Its greatest clinical use to date is the assessment of acute ischemic stroke, and the second greatest is diagnosis of brain tumors and their effects on movement, language, and vision. DTI is employed by neurosurgeons for locating tumors and lesions that don't show up on conventional MRI. This enables the surgeon to precisely target a problem area and avoid injury to other critical tracts nearby. It is helpful in monitoring the maturation of myelin in children, degenerative changes in old age, the progress of demyelinating diseases such as multiple sclerosis, the extent of traumatic brain injury (TBI), and brain responses to therapy. It has found clinical applications as well to Alzheimer disease, epilepsy, autism, and cocaine addiction. Clinicians hope that it will prove useful in the prognosis of diseases—predicting their developmental course to allow for earlier and more effective intervention. DTI has also been used in assessments of cardiac muscle, prostate disease, and athletic injuries to muscles and tendons.

FIGURE 14.15 Histology of the Neocortex. Neurons are arranged in six layers. Compare the opening photo of chapter 12.

? Note the long processes leading upward from each pyramidal cell body. Are those axons or dendrites? Explain your answer.

mammals. It attained its highest development by far in the primates. The six layers of neocortex, numbered in figure 14.15, vary from one part of the cerebrum to another in relative thickness, cellular composition, synaptic connections, size of the neurons, and destination of their axons. Layer IV is thickest in sensory regions and layer V in motor regions, for example. All axons that leave the cortex and enter the white matter arise from layers III, V, and VI.

Some regions of cerebral cortex have fewer layers. The earliest type of cortex to appear in vertebrate evolution was a one- to five-layered tissue called *paleocortex* (PALE-ee-oh-COR-tex), limited in humans to part of the insula and certain areas of the temporal lobe concerned with smell. The next to evolve was a three-layered *archicortex* (AR-kee-COR-tex), found in the human hippocampus, a memory-forming center in the temporal lobe. The neocortex was the last to evolve.

The Limbic System

The **limbic**³⁵ **system** is an important center of emotion and learning. It is a ring of structures on the medial side of each hemisphere, encircling the corpus callosum and thalamus. Its most prominent components are the **cingulate**³⁶ **gyrus** (SING-you-let), which arches over the top of the corpus callosum in the frontal and parietal lobes; the **hippocampus**³⁷ in the medial temporal lobe (**fig. 14.16**); and the **amygdala**³⁸ (ah-MIG-da-luh) immediately rostral to the hippocampus, also in the temporal lobe. There are still differences of opinion on what structures to consider as parts of the limbic system, but these three are agreed upon. Other components include the mammillary bodies and other hypothalamic nuclei, some thalamic nuclei, parts of the basal nuclei, and parts of the frontal lobe called *prefrontal* and *orbitofrontal cortex*. Limbic system components are interconnected through a complex loop of fiber tracts allowing for

³⁵limbus = border

³⁶cingul = girdle

³⁷hippocampus = sea horse, named for its shape

³⁸amygdala = almond

FIGURE 14.16 The Limbic System. This ring of structures (shown in violet) includes important centers of learning and emotion. In the frontal lobe, there is no sharp rostral boundary to limbic system components.

somewhat circular patterns of feedback among its nuclei and cortical neurons. All of these structures are bilaterally paired; there is a limbic system in each cerebral hemisphere.

The limbic system was long thought to be associated with smell because of its close association with olfactory pathways, but beginning in the early 1900s and continuing even now, experiments have abundantly demonstrated more significant roles in emotion and memory. Most limbic system structures have centers for both reward and aversion. Stimulation of a reward center produces a sense of pleasure; stimulation of an aversion center produces unpleasant

sensations such as fear or sorrow. Reward centers dominate some limbic structures, such as the *nucleus accumbens* (not illustrated), while aversion centers dominate others such as the amygdala. The roles of the amygdala in emotion and the hippocampus in memory are described in section 14.5d–e.

The Basal Nuclei

The basal nuclei are masses of cerebral gray matter buried deep in the white matter, lateral to the thalamus (**fig. 14.17**). They are often

FIGURE 14.17 The Basal Nuclei. (a) Frontal section of the brain. (b) Corresponding slice of fresh brain tissue. The basal nuclei are labeled in boldface. **APR**

Photo: Biophoto Associates/Science Source

called **basal ganglia**, but this book restricts the word *ganglion* to clusters of neurons outside the CNS. Neuroanatomists disagree on how many brain centers to classify as basal nuclei, but agree on at least three: the **caudate nucleus**,³⁹ **putamen**⁴⁰ (pyu-TAY-men), and **globus pallidus**.⁴¹ These three are collectively called the *corpus striatum*⁴² because of their striped appearance. The putamen and globus pallidus together are also called the *lentiform*⁴³ **nucleus**, because they form a lens-shaped body. They are involved in motor control and are further discussed in a later section on that topic.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

14. What are the three major components of the diencephalon? Which ventricle does the diencephalon enclose?
15. What is the role of the thalamus in sensory function?
16. List at least six functions of the hypothalamus.
17. Name the five lobes of the cerebrum and describe their locations, boundaries, and principal functions.
18. Distinguish between commissural, association, and projection tracts of the cerebrum.
19. Where is the limbic system located? What component of it is involved in emotion? What component is involved in memory?
20. Where are the basal nuclei located? What is their general function?

14.5 Integrative Functions of the Brain

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. list the types of brain waves and discuss their relationship to mental states;
- b. describe the stages of sleep, their relationship to the brain waves, and the neural mechanisms of sleep;
- c. identify the brain regions concerned with consciousness and thought, memory, emotion, sensation, motor control, and language; and
- d. discuss the functional differences between the right and left cerebral hemispheres.

This section concerns such “higher” brain functions as sleep, memory, cognition, emotion, sensation, motor control, and language. These are associated especially with the cerebral cortex, but not

exclusively; they involve interactions between the cerebral cortex and such areas as the basal nuclei, brainstem, and cerebellum. It is impossible in many cases to assign these functions to one specific brain region; as we have already seen, functions of the brain don’t have such easily defined anatomical boundaries. Some functions overlap anatomically and some cross anatomical boundaries from one region to another, often remote region. Thus, we will consider these as *integrative* functions of the brain, focusing especially on the cerebrum but in many cases involving the combined action of multiple levels of the brain. Some of these present the most difficult challenges for neurobiology, but they are the most intriguing functions of the brain and involve its largest areas.

14.5a The Electroencephalogram

For research and clinical purposes, it is common to monitor electrical activity called **brain waves**. Recorded with electrodes on the scalp (**fig. 14.18a**), these are rhythmic voltage changes resulting predominantly from synchronized postsynaptic potentials (not action potentials) in the superficial layers of the cerebral cortex. The recording, called an **electroencephalogram**⁴⁴ (**EEG**), is useful in studying normal brain functions such as sleep and consciousness, and in diagnosing degenerative brain diseases, metabolic abnormalities, brain tumors, trauma, and so forth. States of consciousness ranging from high alertness to deep sleep are correlated with changes in the EEG. The complete and persistent absence of brain waves is a common clinical and legal criterion of brain death.

There are four types of brain waves (**fig. 14.18b**), distinguished by differences in amplitude (mV) and frequency. Frequency is expressed in hertz (Hz), or cycles per second:

1. **Alpha (α) waves** have a frequency of 8 to 13 Hz and are recorded especially in the parieto-occipital area. They dominate the EEG when a person is awake and relaxed, with the eyes closed and the mind wandering. They are suppressed when a person opens the eyes, receives specific sensory stimulation, or engages in a mental task such as reading or performing mathematical calculations. They are absent during deep sleep.
2. **Beta (β) waves** have a frequency of 14 to 30 Hz and occur in the frontal to parietal region. They are accentuated during mental activity and sensory stimulation.
3. **Theta (θ) waves** have a frequency of 4 to 7 Hz. They are normal in children and in drowsy or sleeping adults, but a predominance of theta waves in awake adults suggests emotional stress or brain disorders.
4. **Delta (δ) waves** are high-amplitude “slow waves” with a frequency of less than 3.5 Hz. Infants exhibit delta waves when awake, and adults exhibit them in deep sleep. A predominance of delta waves in awake adults indicates serious brain damage.

³⁹caudate = tailed, tail-like

⁴⁰putam = pod, husk

⁴¹glob = globe, ball; pall = pale

⁴²corpus = body; striat = stripe

⁴³lenti = lens; form = shape

14.5b Sleep

Sleep can be defined as a temporary, reversible loss of consciousness from which (in contrast to coma) one can awaken when stimulated. It is one of many bodily functions that occur in cycles called **circadian**⁴⁵ **rhythms** (sur-CAY-dee-an), so named because they are marked by events that recur at intervals of about 24 hours. Sleep superficially resembles other states of prolonged unconsciousness such as coma and animal hibernation, except that individuals cannot be aroused from those states by sensory stimulation.

Sleep occurs in distinct stages recognizable from changes in the EEG. In the first 30 to 45 minutes, the EEG waves drop in frequency but increase in amplitude as one passes through four sleep stages (**fig. 14.19a**):

- **Stage 1.** This stage usually lasts for 1 to 7 minutes. One feels drowsy, closes the eyes, and begins to relax. The EEG transitions from alpha waves to waves of mixed frequency. Thoughts come and go, often accompanied by a drifting sensation. One awakens easily if stimulated.
- **Stage 2.** This stage usually lasts for 10 to 25 minutes in the initial sleep cycle. One passes into light sleep. Brain waves have a lower frequency but higher voltage. They occasionally show 1 or 2 seconds of *sleep spindles*, high spikes resulting from interactions between neurons of the thalamus and cerebral cortex.
- **Stage 3.** This is moderate to deep sleep, typically beginning about 20 minutes after stage 1. Sleep spindles occur less

often, and theta and delta waves appear. The muscles relax, and the *vital signs* (body temperature, blood pressure, and heart and respiratory rates) fall.

- **Stage 4.** The muscles are now very relaxed, vital signs are at their lowest levels, and one becomes difficult to awaken. Stage 4 sleep usually occurs only in the first one-third of the night (**fig. 14.19b**).

About five times a night, a sleeper backtracks from stage 3 or 4 to stage 2 and exhibits bouts of **rapid eye movement (REM) sleep**. This is so named because the eyes oscillate back and forth as if watching a movie. It is also called *paradoxical sleep* because the EEG resembles the waking state, yet the sleeper is harder to arouse than in any other stage. Vital signs increase and the brain consumes even more oxygen than when awake. Sleep paralysis is especially strong during REM sleep and usually prevents the sleeper from acting out his or her dreams.

Bouts of REM sleep become longer and longer as the night progresses, and we usually wake in the morning from either stage 3 or REM sleep. Dreams occur in both REM and non-REM sleep, but REM dreams tend to be longer, more vivid, and more emotional than non-REM dreams. Most frightening dreams (nightmares), however, occur during non-REM sleep. The parasympathetic nervous system is very active during REM sleep, causing constriction of the pupils and erection of the penis or clitoris. Erection, however, is seldom accompanied by sexual dream content.

Humans are a diurnal (daytime-active) species in whom falling light intensity induces sleepiness. As the light fades at the end of the day, certain retinal cells called *ganglion cells* transmit signals to part of the hypothalamus called the **suprachiasmatic nucleus (SCN)** (SOO-pra-KY-az-MAT-ic) (see **fig. 14.12b**).

⁴⁵*circa* = approximately; *dia* = a day, 24 hours

FIGURE 14.19 Sleep Stages and Brain Activity. (a) A single sleep cycle, from waking to deep sleep, followed by 10 minutes of REM sleep. (b) Stages of sleep over an 8-hour night in a typical young adult. Stage 4 is attained only in the first two cycles. Periods of REM sleep increase from about 10 minutes in the first cycle to as long as 50 minutes in the last hour of sleep. Most dreaming occurs during REM sleep.

Located just above the optic chiasm, the SCN is the body's master biological clock. It regulates not only sleep but also circadian rhythms of body temperature, urine production, hormone secretion, and other functions.

The SCN has two major output pathways leading to the nearby *dorsomedial nucleus (DMN)* and the *pineal gland*. The pineal gland responds to SCN input by secreting the hormone **melatonin**. Melatonin and the DMN together act on the reticular activating system (RAS) of the brainstem. The RAS now blocks signals from the thalamus to the cerebral cortex, so a drowsy person becomes less and less aware of environmental stimuli and lapses into sleep.

Waking is brought on by **orexins**, neuropeptides secreted by the hypothalamus. These stimulate the reticular activating

system, which then stimulates the thalamus. As a person begins to wake, electrical activity increases in the thalamus and then spreads through the cerebral cortex. Thus, the cerebral awareness of environmental stimuli increases and the sleeper wakes up. The excitatory pathway from RAS to thalamus and cortex involves multiple excitatory neurotransmitters including histamine; this is why antihistamines, antagonizing this pathway, can make one drowsy.

Orexins are absent or at low levels in a disorder called **narcolepsy**, in which a person experiences excessive daytime sleepiness and fatigue and may often fall asleep at work or school, with abnormally quick onset of REM sleep. Narcolepsy seems to be an autoimmune disease caused by antibody-mediated destruction of the orexin-producing neurons.

▶▶▶ APPLY WHAT YOU KNOW

Some animals have been shown to exhibit narcolepsy as the result of a mutation in the gene for an orexin receptor. Looking ahead in the book to type 2 diabetes mellitus in section 17.7e, can you identify a common thread in these two disorders?

We spend about one-third of our lives asleep, and we might well regret such a terrible “waste of time.” Yet sleep deprivation can cause widespread dysfunctions ranging from cognitive decline or hallucinations to weight loss, reduced immunity, and even death. Yet the reasons for sleep and dreaming remain elusive. Non-REM sleep has a restorative, refreshing effect, but it is unclear why quiet bed rest alone can’t serve these purposes. Why must we lose consciousness?

Sleep is associated with restorative anabolic processes in the immune, nervous, endocrine, and other systems. Growth hormone secretion, and presumably its anabolic effects, rise during slow-wave sleep. During waking hours, brain glycogen levels go down, while ATP consumption generates a sleep-inducing metabolite, adenosine (see Deeper Insight 15.2). Non-REM sleep reduces cerebral metabolic rate and ATP consumption, allowing glycogen and ATP levels to rebound while adenosine levels fall and other metabolites are cleared from the brain. The recent discovery and research on the *glymphatic system* supports the idea of a waste-removal function of sleep (see section 21.1b).

Sleep also plays an important role in memory. REM sleep appears to be a time in which the brain either “consolidates” and strengthens memories by reinforcing synaptic connections, or purges superfluous information from memory by weakening or eliminating other synapses. When REM sleep is blocked in experimental animals without waking them, they forget tasks they had recently learned. Theta wave activity and the sleep spindles of stage 2 sleep are also associated with memory consolidation. Sleep research subjects who have just learned a new task show a higher density of sleep spindles than controls who have not.

14.5c Cognition

Cognition⁴⁶ consists of the mental processes by which we acquire and use knowledge—sensory perception, thought, reasoning, judgment, memory, imagination, and intuition. Such functions are widely distributed over regions of cerebral cortex called **association areas**, which constitute about 75% of all brain tissue. This is the most difficult area of brain research and the most incompletely understood aspect of cerebral function. Much of what we know about it has come from studies of patients with brain lesions—areas of tissue destruction resulting from cancer, stroke, and trauma. The many brain injuries incurred in World Wars I and II yielded an abundance of insights into regional brain functions. More recently, imaging methods such as PET and fMRI have yielded much more sophisticated insights into brain function in normal, healthy individuals, ending reliance on studies of seriously wounded persons. These methods allow a researcher to scan a person’s brain during various cognitive or

motor tasks and to see which brain regions are most active in different mental and task states (see Deeper Insight 14.5).

A few examples of the cognitive effects of cerebral lesions reveal some functions of the association areas:

- Parietal lobe lesions can cause people to become unaware of objects, or even their own limbs, on the other side of the body—a condition called *contralateral neglect syndrome*. In typical cases, men shave only half of the face, women apply makeup to only one side, patients dress only half of the body, and some people deny that one arm or leg belongs to them. Such patients are unable to find their way around—say, to describe the route from home to work or navigate within a familiar building.
- Temporal lobe lesions often result in *agnosia*⁴⁷ (ag-NO-zee-ah), the inability to recognize, identify, and name familiar objects. In *prosopagnosia*,⁴⁸ people can’t remember familiar faces, even their own reflection in a mirror.
- Frontal lobe lesions are especially devastating to the qualities we think of as personality. The frontal lobe integrates information from sensory and motor regions of the cortex and from other association areas. It gives us a sense of our relationship to the rest of the world, enabling us to think about it and to plan and execute appropriate behavior. Lesions here may produce profound personality disorders and socially inappropriate behaviors.

14.5d Memory

Memory is one of the cognitive functions, but warrants special attention. We studied its forms and its neural and molecular mechanisms in chapter 12. Now that you have been introduced to the gross anatomy of the brain, we can consider where those processes occur anatomically.

Our subject is really a little broader than memory per se. Information management by the brain entails learning (acquiring new information), memory proper (information storage and retrieval), and forgetting (eliminating trivial information). Brain-injured people are sometimes unable to recall things they once knew (**retrograde amnesia**) or unable to store new information (**anterograde amnesia**). *Amnesia* refers to defects in *explicit* memory (such as the ability to describe past events), not *implicit* memory (such as the ability to tie one’s shoes).

The **hippocampus** of the limbic system is an important memory-forming center (see fig. 14.16). It doesn’t store memories, but organizes sensory and cognitive experiences into a unified long-term memory. The hippocampus learns from sensory input while an experience is happening, but it has a short memory. Later, especially during sleep, it plays this memory repeatedly to the cerebral cortex, which is a “slow learner” but forms longer-lasting memories. This process of “teaching the cerebral cortex” until a long-term memory is established is called **memory consolidation**. Long-term memories are held in various areas of cortex. One’s vocabulary and memory of faces and familiar

⁴⁶cognit = to know

⁴⁷a = without; gnos = knowledge

⁴⁸prosopo = face, person

objects, for example, reside in the superior temporal lobe, and memories of one's plans and social roles are in the prefrontal cortex (see fig. 14.13).

Lesions of the hippocampus can cause profound anterograde amnesia. For example, in 1953, a famous patient known in the literature as H. M. (Henry Molaison, 1926–2008) underwent surgical removal of a large portion of both temporal lobes, including both hippocampi, to treat severe epilepsy. The operation had no adverse effect on his intelligence or explicit memory for things that had happened early in his life, but it left him with an inability to establish new explicit memories. He worked with the same psychologist for more than 40 years after his operation, but couldn't remember who she was from day to day or remember a conversation they had only a few minutes earlier. He was nevertheless able to learn new motor skills, thus showing explicit and implicit memory to involve separate brain regions.

Other parts of the brain involved in memory include the cerebellum, with a role in learning motor skills, and the amygdala, with a role in emotional memory.

14.5e Emotion

Emotional feelings and memories aren't exclusively cerebral functions, but result from an interaction between areas of the prefrontal cortex and diencephalon. Emotional control centers of the brain have been identified by studying people with brain lesions and by such techniques as surgical removal, ablation (destruction) of small regions with electrodes, and stimulation with electrodes and chemical implants, especially in experimental animals. Changes in behavior following such procedures give clues to the functions that a region performs. However, interpretation of the results is difficult and controversial because of the complex connections between the emotional brain and other regions.

The **prefrontal cortex (frontal association area)** is the most rostral part of the frontal lobe, just behind the forehead. It is well developed only in primates, especially humans. It is the seat of judgment, intent, and control over the expression of our emotions. However we may feel, it is here that we decide the appropriate way to show those feelings. But the feelings themselves, and emotional memories, arise from deeper regions of the brain, especially the hypothalamus and amygdala. Here lie the nuclei that stimulate us to recoil in fear from a rattlesnake or yearn for a lost love.

The amygdala is a major component of the limbic system described earlier (see fig. 14.16). It receives processed information from the general senses and from vision, hearing, taste, and smell. Such input enables it to mediate emotional responses to such stimuli as a disgusting odor, a foul taste, a beautiful sight, pleasant music, or a stomachache. It is especially important in the sense of fear, but also plays roles in decision making, food intake, sexual behavior, empathy, sensing the emotional state of others, and drawing our attention to novel stimuli.

Output from the amygdala goes in two directions of special interest: (1) Some goes to the hypothalamus and lower brainstem and influences somatic and visceral motor systems. An emotional response to a stimulus may, through these connections, make one's heart race, raise the blood pressure, make the hair stand on end, or

induce vomiting. (2) Other output goes to areas of the prefrontal cortex that mediate conscious control and expression of the emotions, such as the ability to express love, control anger, or overcome fear.

Many important aspects of personality depend on an intact, functional amygdala and hypothalamus. When specific regions are destroyed or artificially stimulated, humans and other animals exhibit either blunted or exaggerated expressions of anger, fear, aggression, self-defense, pleasure, pain, love, sexuality, and parental affection, as well as abnormalities in learning, memory, and motivation. Lesions of the amygdala, for example, can abolish the sense of fear.

Much of our behavior is shaped by learned associations between stimuli, our responses to them, and the rewards or punishments that result. Nuclei involved in feelings of reward and punishment have been identified in the hypothalamus of cats, rats, monkeys, and other animals. In a representative experiment, an electrode is implanted in an area of an animal's hypothalamus called the **median forebrain bundle (MFB)**. The animal is placed in a chamber with a foot pedal wired to that electrode. When the animal steps on the pedal, it receives a mild electrical stimulus to the MFB. Apparently the sensation is strongly rewarding, because the animal soon starts to press the pedal over and over and may spend most of its time doing so—even to the point of neglecting food and water. Rats have been known to bar-press 5,000 to 12,000 times an hour, and monkeys up to 17,000 times an hour, to stimulate their MFBs.

These animals cannot tell us what they are feeling, but electrode implants have also been used to treat people who suffer otherwise incurable schizophrenia, pain, or epilepsy. These patients also repeatedly press a button to stimulate the MFB, but they don't report feelings of joy or ecstasy. Some are unable to explain why they enjoy the stimulus, and others report "relief from tension" or "a quiet, relaxed feeling." With electrodes misplaced in other areas of the hypothalamus, subjects report feelings of fear or terror when stimulated.

▶▶▶ APPLY WHAT YOU KNOW

MRI scans show that John has a pea-size tumor in his hippocampus, and Allan has a tumor of the same size in his amygdala. One of these patients is in prison for violent crimes in which he seemed to show no fear or sense of self-preservation. The other patient can't remember the name of his new granddaughter, no matter how many times he is told. Which behavioral outcome do you associate with each patient? Why?

14.5f Sensation

A great deal of the cerebrum is concerned with the senses—most cortex of the insula and of the parietal, occipital, and temporal lobes. Regions called **primary sensory cortex** are the sites where sensory input is first received and one becomes conscious of a stimulus. Adjacent to these are association areas where this information is interpreted. For example, the primary visual cortex, which receives input from the eyes, is bordered by the visual association area, which interprets and makes cognitive sense of the visual stimuli so we know what we are looking at. Some association

FIGURE 14.20 Some Functional Regions of the Left Cerebral Cortex. The Broca and Wernicke areas for language abilities are found in only one hemisphere, usually the left. The other regions shown here are mirrored in both hemispheres.

areas are *multimodal*—instead of processing information from a single sensory source, they receive input from multiple senses and integrate this into our overall perception of our surroundings. For example, in the frontal lobe just above the eyes, there is a patch of multimodal cortex called the *orbitofrontal cortex*, which receives taste, smell, and visual input to form our overall impression of the desirability of a particular food.

The sense organs and their signaling pathways in the CNS are the subject of chapter 16. Here we will examine only the areas of cerebral cortex involved in sensory perception.

The Special Senses

The **special senses** are vision, hearing, equilibrium, taste, and smell. They are collectively defined as senses limited to the head and employing relatively complex sense organs. Their primary cortices and association areas are located as follows (**fig. 14.20**).

- **Vision.** Visual signals are received by the **primary visual cortex** in the far posterior region of the occipital lobe. This is bordered anteriorly by the **visual association area**, which includes all the remainder of the occipital lobe, some of the posterior parietal lobe (concerned with spatial perception), and much of the inferior temporal lobe, where we recognize faces and other familiar objects.
- **Hearing.** Auditory signals are received by the **primary auditory cortex** in the superior region of the temporal lobe and in the nearby insula. The **auditory association area** occupies areas of temporal lobe inferior to the primary auditory cortex and deep within the lateral sulcus. Here resides our ability to recognize spoken words, a familiar piece of music, or a voice on the telephone.

- **Equilibrium.** Signals from the inner ear for equilibrium project mainly to the cerebellum and several brainstem nuclei concerned with head and eye movements and visceral functions. Some fibers of this system, however, are routed through the thalamus to areas of association cortex in the roof of the lateral sulcus and near the lower end of the central sulcus. This is the seat of consciousness of our body movements and orientation in space.
- **Taste and smell.** Gustatory (taste) signals are received by the **primary gustatory cortex** in the inferior end of the postcentral gyrus of the parietal lobe (discussed shortly) and an anterior region of the insula. Olfactory (smell) signals are received by the **primary olfactory cortex** in the medial cortex of the temporal lobe and inferior cortex of the frontal lobe. The *orbitofrontal cortex* mentioned earlier serves as a multimodal association area for both taste and smell, and is thus highly important in our enjoyment or rejection of various foods and drinks.

The General Senses

The **general (somatosensory, somesthetic,⁴⁹ or somatic) senses** are distributed over the entire body and employ relatively simple receptors. They include such senses as touch, pressure, stretch, movement, heat, cold, and pain. Coming from the head, such signals reach the brain by way of certain cranial nerves, especially the trigeminal nerve; from the rest of the body, they ascend sensory tracts of the spinal cord such as the spinothalamic tract. In both routes, they decussate to the contralateral thalamus.

⁴⁹som = body; esthet = feeling

FIGURE 14.21 The Primary Somatosensory Cortex (Postcentral Gyrus). (a) Superior view of the brain showing the location of the postcentral gyrus (violet). (b) Anterior view of the sensory homunculus in the right hemisphere, drawn so that body parts are in proportion to the amount of cortex dedicated to their sensation. This gyrus also includes centers for visceral sensation from the intra-abdominal organs (the viscerosensory area). **APR**

The thalamus processes the input and selectively relays signals to the **postcentral gyrus**. This is a fold of the cerebrum that lies immediately posterior to the central sulcus and thus forms the rostral border of the parietal lobe (**fig. 14.21**). We can trace it from just above the lateral sulcus to the crown of the head and then down into the longitudinal cerebral fissure. Its cortex is called the **primary somatosensory cortex**. Adjacent to it is a **somatosensory association area**, caudal to the gyrus and in the roof of the lateral sulcus (**fig. 14.20**). Awareness of stimulation occurs in the primary somatosensory cortex, but making cognitive sense of it is a function of the association area.

Because of the aforementioned decussation in sensory pathways, the right postcentral gyrus receives input from the left side of the body and vice versa. The primary somatosensory cortex is like an upside-down sensory map of the contralateral side of the body, traditionally diagrammed as a *sensory homunculus*⁵⁰ (**fig. 14.21b**). As the diagram shows, receptors in the lower limb project to superior and medial parts of the gyrus, and receptors in the face project to the inferior and lateral parts. Such point-for-point correspondence between an area of the body and an area of the CNS is called **somatotopy**.⁵¹ The reason for the bizarre, distorted appearance of the homunculus is that the amount of cerebral tissue devoted to a given body region is proportional to how richly innervated and

sensitive that region is, not to its size. Thus, the hands and face are represented by a much larger region of somatosensory cortex than the trunk is and are drawn larger in the homunculus.

14.5g Motor Control

The intention to contract a skeletal muscle begins in the **motor association (premotor) area** of the frontal lobe (**fig. 14.20**). This is where we plan our behavior—where neurons compile a program for the degree and sequence of muscle contractions required for an action such as dancing, typing, or speaking. The program is then transmitted to neurons of the **precentral gyrus (primary motor area)**, which is the most posterior gyrus of the frontal lobe, immediately anterior to the central sulcus (**fig. 14.22**). Neurons here send signals to the brainstem and spinal cord, which ultimately results in muscle contractions.

The precentral gyrus, like the postcentral one, exhibits somatotopy. The neurons for toe movements, for example, are deep in the longitudinal cerebral fissure on the medial side of the gyrus. The summit of the gyrus controls the trunk, shoulder, and arm, and the inferolateral region controls the facial muscles. This map is diagrammed as a *motor homunculus* (**fig. 14.22b**). Like the sensory homunculus, it has a distorted look because the amount of cortex devoted to a given body region is proportional to the number of muscles and motor units in that region, not to the size of the region. The amount of cerebral tissue dedicated to the hands, face,

⁵⁰hom = man; uncus = little

⁵¹somato = body; topy = place

FIGURE 14.22 The Primary Motor Cortex (Precentral Gyrus). (a) Superior view of the brain showing the location of the precentral gyrus (blue). (b) Motor homunculus, drawn so that body parts are in proportion to the amount of primary motor cortex dedicated to their control. **APR**

? Which body regions are controlled by the largest areas of motor cortex—regions with a few large muscles or regions with numerous small muscles?

and tongue reflects the importance of fine motor control in speech, facial expression, and use of the hands.

There is no exact point-for-point correspondence between an area of the precentral gyrus and a given muscle. A muscle is controlled by neurons at several points within a general area of the gyrus. Also, a given neuron in the gyrus may ultimately affect more than one muscle, such as muscles of shoulder and elbow movement that both contribute to the coordinated positioning of one's hand. Although the homunculus identifies cortical areas that are broadly responsible for motor control of a given region, the boundaries between these cortical areas overlap and aren't sharply defined.

The pyramidal cells of the precentral gyrus are called **upper motor neurons**. Their fibers (axons) project caudally, with about 19 million fibers ending in nuclei of the brainstem and 1 million forming the corticospinal tracts. Most of these fibers decussate in the lower medulla oblongata (at the pyramidal decussation) and form the *lateral corticospinal tract* on each side of the spinal cord. A smaller number of fibers pass through the medulla without decussation and form the *anterior corticospinal tracts*, which cross over lower in the spinal cord. Each precentral gyrus thus controls muscles on the contralateral side of the body. In the brainstem or spinal cord, the fibers from the upper motor neurons synapse with **lower motor neurons** whose axons are the somatic motor nerve fibers that innervate the skeletal muscles (see fig. 13.7).

Other areas of the brain important in muscle control are the basal nuclei (see fig. 14.17) and cerebellum. Among the roles of the basal nuclei are determining the onset and cessation of intentional movements; the repetitive hip and shoulder movements that occur in walking; and highly practiced, learned behaviors that one carries out with little thought—for example, writing, driving a car, and tying one's shoes. The basal nuclei lie in a feedback circuit from the cerebrum to the basal nuclei to the thalamus and back to the cerebrum. They receive signals from the substantia nigra of the midbrain and from all areas of cerebral cortex, except for the primary visual and auditory cortices. The basal nuclei process these and issue their output to the thalamus, which relays these signals back to the midbrain and cerebral cortex—especially to the prefrontal cortex, motor association area, and precentral gyrus.

Lesions of the basal nuclei cause movement disorders called **dyskinesias**.⁵² These are sometimes characterized by abnormal difficulty initiating movement, such as rising from a chair or beginning to walk, and by a slow shuffling walk. Such motor dysfunctions are seen in Parkinson disease. Smooth, easy movements require the excitation of agonistic muscles and inhibition of their antagonists. In Parkinson disease, the antagonists are not inhibited. Therefore,

⁵²*dys* = bad, abnormal, difficult; *kines* = movement

FIGURE 14.23 Motor Pathways Involving the Cerebellum. (a) Afferent (input) pathways from the cerebrum and sense organs to the cerebellum. (b) Efferent (output) pathways from the cerebellum to the skeletal muscles.

opposing muscles at a joint fight each other, making it a struggle to move as one wishes. Other dyskinesias are characterized by exaggerated or unwanted movements, such as flailing of the limbs (*ballismus*) in Huntington disease.

The cerebellum is highly important in motor coordination. In addition to its cognitive functions described earlier (see section 14.3e), it aids in learning motor skills, maintains muscle tone and posture, smooths muscle contractions, coordinates eye and body

movements, and helps to coordinate the motions of different joints with each other (such as the shoulder and elbow in pitching a baseball). The cerebellum acts as a comparator in motor control. Through the middle peduncles, it receives information from the upper motor neurons of the cerebrum about the movements one intends to make, and information about body movement from the eyes and inner ears. Through the spinocerebellar tracts and inferior peduncles, it receives information from proprioceptors in the muscles and joints about the actual performance of the movement (**fig. 14.23a**). The Purkinje cells of the cerebellum compare the two. If there is a discrepancy between the intent and the performance, they signal the deep cerebellar nuclei. These, in turn, issue signals to the thalamus and lower brainstem, ultimately ascending to the motor association area of the cerebrum and the reticulospinal and vestibulospinal tracts of the spinal cord (**fig. 14.23b**). Output from these areas corrects the muscle performance to match the intent. Lesions of the cerebellum can result in a clumsy, awkward gait (*ataxia*) and make some tasks such as climbing stairs difficult or impossible.

14.5h Language

Language includes several abilities—reading, writing, speaking, gesturing, sign language, and understanding words—assigned to different regions of cerebral cortex (**fig. 14.24**). The **posterior speech area**, or **Wernicke⁵³ area** (WUR-ni-keh), is responsible for the recognition of spoken and written language. It lies just posterior to the lateral sulcus, usually in the left hemisphere, at the crossroad between visual, auditory, and somatosensory areas of cortex, receiving input from all these neighboring regions. The *angular gyrus*, part of the parietal lobe just caudal and superior to the Wernicke area, is important in the ability to read and write.

When we intend to speak, the Wernicke area formulates phrases according to learned rules of grammar and vocabulary and transmits a plan of speech to the **motor language area**, or **Broca⁵⁴ area**,

located in the inferior prefrontal cortex of the same hemisphere. PET scans show a rise in the metabolic activity of the Broca area as one prepares to speak or sign (see **fig. 14.41**). This area generates a motor program for the muscles of the larynx, tongue, cheeks, and lips to produce speech, as well as for the hand motions of signing. It transmits this program to the primary motor cortex, which executes it—that is, it issues commands to the lower motor neurons that supply the relevant muscles.

The emotional aspect of language is controlled by regions in the opposite hemisphere that mirror the Wernicke and Broca areas. Opposite the Broca area is the *affective language area*. Lesions to this area result in *aprosody*—flat, emotionless speech. The cortex opposite the Wernicke area is concerned with recognizing the emotional content of another person's speech. Lesions here can result in such problems as misreading another person's emotional tone or intention, or inability to understand a joke.

▶▶▶ APPLY WHAT YOU KNOW

Of all the language centers just described, which one best fits the concept of multimodal association cortex?

Aphasia⁵⁵ (ah-FAY-zee-uh) is any language deficit resulting from lesions in the hemisphere (usually the left) containing the Wernicke and Broca areas. The many forms of aphasia are difficult to classify. *Nonfluent (Broca) aphasia*, due to a lesion in the Broca area, results in slow speech, difficulty choosing words, or use of words that only approximate the correct word. For example, a person may say “tssair” when asked to identify a picture of a chair. In extreme cases, the person's entire vocabulary consists of two or three words, sometimes those that were being spoken when a stroke occurred. Such patients feel very frustrated with themselves and often maintain a tight-lipped reluctance to talk. A lesion to the Wernicke area may cause *fluent (Wernicke) aphasia*, in which a person speaks normally and sometimes excessively, but uses jargon and invented words that make little sense (for example,

⁵³Karl Wernicke (1848–1905), German neurologist

⁵⁴Pierre Paul Broca (1824–80), French surgeon and anthropologist

⁵⁵a = without; phas = speech

FIGURE 14.24 Language Centers of the Left Hemisphere.

“choss” for chair). Such a person may be unable to comprehend written and spoken words. In *anomic aphasia*, a person can speak normally and understand speech, but can’t identify written words or pictures. Shown a picture of a chair, the person may say, “I know what it is; I have a lot of them,” but be unable to name the object.

This represents only a small sample of the complex and puzzling linguistic effects of brain lesions. Other lesions to small areas of cortex can cause impaired mathematical ability, a tendency to forget vowels and write only consonants, or difficulty understanding the second half of each word a person reads.

14.5i Cerebral Lateralization

The two cerebral hemispheres look identical at a glance, but close examination reveals a number of differences. For example, in many women the left temporal lobe is longer than the right. In left-handed people, the left frontal, parietal, and occipital lobes are usually wider than those on the right. The two hemispheres also differ in some of their functions (**fig. 14.25**). Neither hemisphere is “dominant,” but each is specialized for certain tasks. This difference in function is called **cerebral lateralization**. The idea, however, that some people are “left-brained” (such as a mathematician or scientist) and others “right-brained” (such as a musician or artist) is only a discredited popular myth. Everyone uses the two hemispheres about equally.

One hemisphere, usually the left, is called the *categorical hemisphere*. It is specialized for spoken and written language and for the sequential and analytical reasoning employed in such fields as science and mathematics. This hemisphere seems to break information into fragments and analyze it in a linear way. The other hemisphere, usually the right, is called the *representational hemisphere*. It perceives information in a more integrated, holistic way. It is a seat of imagination

and insight; musical and artistic skill; perception of patterns and spatial relationships; and comparison of sights, sounds, smells, and tastes. It is better than the left hemisphere at recognizing the intonation, rhythm, and emotional content of other people’s speech.

Cerebral lateralization is highly correlated with handedness. The left hemisphere is the categorical one in 96% of right-handed people, and the right hemisphere in 4%. Among left-handed people, the right hemisphere is categorical in 15% and the left in 70%, whereas in the remaining 15%, neither hemisphere is distinctly specialized.

Lateralization develops with age. In young children, if one cerebral hemisphere is damaged or removed (for example, because of brain cancer), the other hemisphere can often take over its functions. Adult males exhibit more lateralization than females and suffer more functional loss when one hemisphere is damaged. When the left hemisphere is damaged, men are three times as likely as women to become aphasic. The reason for this difference is not yet clear.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

21. Suppose you are reading a novel and gradually fall asleep and begin to dream. How would your brain waves change during this sequence of events?
22. Describe the locations and functions of the somatosensory, visual, auditory, and frontal association areas.
23. Describe the somatotopy of the primary motor area and primary sensory area.
24. What are the roles of the Wernicke area, Broca area, and precentral gyrus in language?

FIGURE 14.25 Lateralization of Cerebral Functions. The two cerebral hemispheres are not functionally identical.

14.6 The Cranial Nerves

Expected Learning Outcomes

When you have completed this section, you should be able to

- list the 12 cranial nerves by name and number;
- identify where each cranial nerve originates and terminates; and
- state the functions of each cranial nerve.

To be functional, the brain must communicate with the rest of the body. Most of its input and output travels by way of the spinal cord, but it also communicates by way of 12 pairs of **cranial nerves**. These arise primarily from the base of the brain, exit the cranium through its foramina, and lead to muscles and sense organs located mainly in the head and neck. The cranial nerves are numbered **CN I** to **CN XII** starting with the most rostral pair (**fig. 14.26**). Each nerve also has a descriptive name such as *optic nerve* and *vagus nerve*.

14.6a Cranial Nerve Pathways

Most motor fibers of the cranial nerves begin in nuclei of the brainstem and lead to glands and muscles. The sensory fibers begin in receptors located mainly in the head and neck and lead mainly to the brainstem. These include the special senses such as vision and hearing, as well as general senses such as touch and proprioception. Pathways for the special senses are detailed in chapter 16. Sensory fibers for proprioception begin in the muscles innervated by motor fibers of the cranial nerves, but they often travel to the brain in a different nerve from the one that supplies the motor innervation.

Most cranial nerves carry fibers between the brainstem and ipsilateral receptors and effectors. Thus, a lesion in one side of the brainstem causes a sensory or motor deficit on the same side of the head. This contrasts with lesions of the motor and somatosensory cortex of the cerebrum, which, as we saw earlier, cause sensory and motor deficits on the *contralateral* side of the body. The exceptions are the optic nerve (II), where half the fibers decussate to the opposite side of the brain (see fig. 16.45), and the trochlear nerve (IV), in which all efferent fibers lead to a muscle of the contralateral eye.

FIGURE 14.26 The Cranial Nerves. (a) Base of the brain, showing the 12 cranial nerves. (b) Photograph of the cranial nerves.

b: Rebecca Gray/Don Kincaid/McGraw Hill

14.6b Cranial Nerve Classification

Cranial nerves are classified as sensory, motor, or mixed according to whether they contain, respectively, only afferent (sensory) nerve fibers, only efferent (motor) fibers, or both. The **sensory nerves** (CN I and II) carry signals only from outlying sense organs to the brain; the **motor nerves** (CN III, IV, VI, XI, and XII) carry signals only from the brainstem to outlying muscles and glands; and the **mixed nerves** (V, VII, VIII, IX, and X) carry signals both ways. Mixed nerves have sensory functions quite unrelated to their motor functions. For example, the facial nerve (CN VII) has a sensory role in taste and a motor role in facial expressions. The vestibulocochlear nerve (CN VIII) for hearing and equilibrium was traditionally classified as purely sensory, but has more recently been found to also have an important motor function in the ear, described shortly.

External to the cranial cavity, the cranial nerves form webs, or *plexuses*, in the head and neck similar to the plexuses of spinal nerves discussed in chapter 13. At their distal terminations in the muscles, motor branches of the cranial nerves often receive sensory fibers from proprioceptors in the muscles. These fibers provide the brain with feedback for controlling muscle action and make one aware of such things as the position of the tongue and orientation of the head. In the plexuses, many fibers cross over from the nerve of origin to a different cranial nerve, often the trigeminal nerve (CN V), that completes their path to the brainstem.

14.6c Cranial Nerve Survey

The following pages survey the key characteristics of each of the 12 pairs of cranial nerves. For each nerve, we begin with a general description of its functions and any unique characteristics it may have; an illustration of its anatomical course; and remarks on the effects of damage to that nerve and how neurologists assess its functionality or deficits. At the end of the descriptive survey, you will find a summary table and illustration, as well as a helpful mnemonic for remembering the names of these nerves in anatomical order.

The Olfactory Nerve (CN I)

The olfactory nerve (**fig. 14.27**) is a purely sensory nerve for smell. It consists of several separate fascicles that pass independently through the cribriform plate of the ethmoid bone in the roof of the nasal cavity. It isn't visible on isolated brains because these fascicles are severed by removal of the brain from the skull, but on most such brains one can see the *olfactory bulbs* in which these nerves end.

FIGURE 14.27 The Olfactory Nerve (I). **APR**

FIGURE 14.28 The Optic Nerve (II). **APR**

The olfactory nerve can be damaged by sharp blows to the face that break the ethmoid bone, such as a person might suffer in striking an automobile dashboard in a collision. Such damage can cause **anosmia**, loss of the sense of smell. This not only diminishes some of life's pleasures, but can also be dangerous if a person fails to detect smoke, a gas leak, or spoiled food. A clinical sign of olfactory nerve damage is that a patient can't smell even such strongly aromatic substances as coffee, vanilla, clove oil, or soap.

The Optic Nerve (CN II)

Four of the 12 cranial nerves (II, III, IV, and VI) are concerned exclusively with the eyes. The only sensory nerve among these is the **optic nerve** (**fig. 14.28**), which carries all visual signals from the retina to the brain. Damage to this nerve causes blindness in part or all of the visual field in the affected eye. Part of the optic nerve, the optic disc, can be seen and assessed in an eye examination with an ophthalmoscope (see **fig. 16.30**). Optic nerve function is also assessed by tests of visual acuity and range of peripheral vision. The optic nerve is now known to contain some parasympathetic (motor) nerve fibers of uncertain function, possibly control of blood vessels in the nerve.

The Oculomotor Nerve (CN III)

The **oculomotor**⁵⁶ nerve (**fig. 14.29**) is motor. It controls four of the six muscles of eye movement (see **fig. 16.25**), which direct the gaze up, down, and medially. It also controls the *levator palpebrae superioris* muscle of the upper eyelid, which opens the eye and holds it open, and the internal eye muscles of focusing and pupillary diameter.

Clinical signs of damage to this nerve include inability to move the eye in the aforesaid directions or to track a moving object, a drooping eyelid, a fixed and dilated pupil, unequal size and shape of the right and left pupils, lack of pupillary responses to light, double vision, difficulty focusing, and a tendency of the eye to rotate laterally at rest.

⁵⁶oculo = eye; motor = mover

FIGURE 14.29 The Oculomotor Nerve (III). **APR**

The Trochlear Nerve (CN IV)

The **trochlear**⁵⁷ nerve (TROCK-lee-ur) (**fig. 14.30**), like the oculomotor, is a motor nerve for eye movement, but its only action is to direct the gaze slightly downward and rotate the top of the eyeball toward the nose, especially in compensating for head movements. This is the only cranial nerve that arises from the posterior side of the brainstem. It is also unique in being the only one to completely decussate; the trochlear nerve roots cross each other within the brainstem before emerging from the surface, so the left trochlear nerve controls the right eye and vice versa.

Signs of trochlear nerve damage include double vision and a weak ability to look downward. The affected eye often points superolaterally and a patient tends to tuck in the chin and tilt the head downward to minimize the double vision. One assessment of trochlear nerve function is *Bielschowsky's head tilt test*—if the

FIGURE 14.30 The Trochlear Nerve (IV). The tendon of the superior oblique muscle passes through a fibrous pulleylike sling, the trochlea (best seen in figure 16.25). **APR**

subject tilts the head toward one shoulder, the eye on that side shows an upward deviation.

The Trigeminal Nerve (CN V)

The **trigeminal**⁵⁸ nerve (tri-JEM-ih-nul) is the largest of all cranial nerves and the most important sensory nerve of the face. Its name refers to the fact that it divides into three prominent branches shortly after leaving the brainstem—the *ophthalmic* (V_1), *maxillary* (V_2), and *mandibular* (V_3) divisions (**fig. 14.31a**). V_1 and V_2 are sensory nerves, whereas V_3 is mixed. Dental pain is felt through the trigeminal nerve. Damage to one of its divisions results in loss of sensation from the respective region of the face (**fig. 14.31b**). Division V_3 also has a motor function in mastication (**fig. 14.31c**), which is impaired by damage to this branch.

⁵⁷trochlea = pulley (for a loop through which the muscle's tendon passes)

⁵⁸tri = three; gem = born (*trigem* = triplets)

FIGURE 14.31 The Trigeminal Nerve (V). Note the three prominent branches, V_1 to V_3 , which give this nerve its name. (a) Anatomical course of the three branches of the trigeminal nerve. (b) Distribution of sensory fibers of each division. (c) Motor branches of the mandibular division (V_3). **APR**

One sign of damage to the V_1 branch is absence of the blink reflex, as when a neurologist touches the eye surface with a cotton wisp. V_2 damage is marked by loss of the senses of touch, pain (tested with pinpricks), and temperature (hot and cold). V_3 is assessed by palpating the masseter and temporalis muscles to feel for muscle tone when the subject clenches the teeth, and testing the ability to move the mandible from side to side and to open the mouth against resistance. The trigeminal nerve is the source of a common pain disorder called *trigeminal neuralgia* (see Deeper Insight 14.4).

The Abducens Nerve (CN VI)

The **abducens**⁵⁹ nerve (ab-DOO-senz) (fig. 14.32), like the oculomotor and trochlear, is also a motor nerve for eye movement.

FIGURE 14.32 The Abducens Nerve (VI). By innervating the lateral rectus muscle, this nerve makes the eye turn away from the facial midline, as its name implies (“to turn away”). **APR**

It controls a muscle, the *lateral rectus*, that directs the gaze laterally. Damage to this nerve causes a medial deviation of the eye, as the medial rectus muscle is unopposed by the lateral rectus. Abducens nerve function is assessed by testing the subject’s ability to direct the gaze laterally.

The Facial Nerve (CN VII)

The **facial nerve** (fig. 14.33) is the major motor nerve to the facial muscles (see table 10.1), but also contains sensory fibers

(a)

(b)

(c)

FIGURE 14.33 The Facial Nerve (VII). (a) The facial nerve and associated organs. (b) The five major branches of the facial nerve. (c) A way to remember the distribution of the five major branches. **APR**

c: Joe DeGrandis/Ken Saladin

⁵⁹ab = away; duc = to lead or turn

FIGURE 14.34 The Vestibulocochlear Nerve (VIII). Note how the nerve arises by convergence of the vestibular nerve and cochlear nerve, as its name implies. **APR**

from taste buds of the anterior two-thirds of the tongue. Thus, it is classified as a mixed nerve. It divides into five prominent branches: the *temporal*, *zygomatic*, *buccal*, *mandibular*, and *cervical* branches. Damage to the facial nerve can distort a person's sense of taste, especially for sweets, and cause sagging of facial muscles for lack of muscle tone (see Deeper Insight 14.4).

Motor functionality of the facial nerve is assessed by testing the subject's ability to smile, frown, whistle, raise the eyeballs, close the eyes, and perform other facial actions. Sensory function is assessed by testing sensitivity of the anterior tongue to substances such as sugar, salt, vinegar, and quinine, and testing the response of the tear glands to ammonia fumes.

The Vestibulocochlear Nerve (CN VIII)

The **vestibulocochlear**⁶⁰ nerve (vess-TIB-you-lo-COC-lee-ur) (**fig. 14.34**) is a predominantly sensory nerve of hearing and equilibrium, but it also has a motor effect on the inner ear to tune the sense of hearing (see chapter 16). Thus, it is a mixed nerve. It forms by convergence of the *cochlear nerve* from the cochlea and *vestibular nerve* from the semicircular ducts and vestibule of the inner ear. Damage to this nerve can cause *sensorineural deafness* (see Deeper Insight 16.2), dizziness, nausea, and *nystagmus* (involuntary rhythmic oscillations of the eyes from side to side). CN VIII function is assessed by looking for nystagmus and testing a patient's hearing, balance, and ability to walk a straight line.

The Glossopharyngeal Nerve (CN IX)

The **glossopharyngeal**⁶¹ nerve (GLOSS-oh-fah-RIN-jee-ul) (**fig. 14.35**) is a complex, mixed nerve with numerous sensory and motor functions in the head, neck, and thoracic region, including sensations from the tongue, throat, and outer ear; control of food intake; and even some aspects of cardiovascular and respiratory function. Signs of damage to this nerve include difficulty swallowing and loss of the bitter and sour taste sensations. It can be assessed by testing the rear of the tongue with bitter and sour substances, noting any speech impediments, and testing the gag reflex, swallowing, and coughing.

FIGURE 14.35 The Glossopharyngeal Nerve (IX). Note how the nerve branches go to the tongue and pharynx, as its name implies. **APR**

The Vagus Nerve (CN X)

The **vagus**⁶² nerve (VAY-gus) (**fig. 14.36**) has the most extensive distribution of all cranial nerves, supplying organs not only in the head and neck but also most viscera of the thoracic and abdominopelvic cavities. It is a mixed nerve with major roles in the control of cardiac, pulmonary, digestive, and urinary functions. It carries somatic nerve fibers to several muscles of the head and neck, as well as 90% of all fibers of the parasympathetic nervous system (see chapter 15).

Damage to both vagus nerves (right and left) is generally fatal. Signs of damage to just one vagus nerve include impaired swallowing and gastrointestinal motility, and hoarseness or loss of the voice. Vagal function is assessed by examining movements of the palate during speech; observing hoarseness or weakness of the voice or the inability to cough forcibly; and checking for swallowing difficulty or absence of the gag reflex.

⁶⁰vestibulo = entryway (vestibule of inner ear); cochlea = conch, snail (cochlea of ear)

⁶¹glosso = tongue; pharyng = throat

⁶²vag = wandering

FIGURE 14.36 The Vagus Nerve (X). Note how this nerve “wanders” through much of the thoracic and abdominal cavities, as its name implies. **APR**

The Accessory Nerve (CN XI)

The **accessory nerve** (fig. 14.37) takes an unusual path. It arises not from the brain but from the upper spinal cord; therefore, strictly speaking, it’s not a true cranial nerve. It ascends alongside the spinal cord, enters the cranial cavity through the foramen magnum, then exits the cranium through the jugular foramen, bundled with the vagus and glossopharyngeal nerves. The accessory nerve is a motor nerve that controls mainly swallowing and some neck and shoulder muscles.

Signs of damage to the accessory nerve include difficulty moving the head, neck, and shoulders. Damage can paralyze the sternocleidomastoid muscle, causing the contralateral sternocleidomastoid to turn the head toward the injured side. Accessory nerve function can be assessed by testing the subject’s ability to rotate the head and shrug the shoulders against resistance.

The Hypoglossal Nerve (CN XII)

The **hypoglossal**⁶³ nerve (HY-po-GLOSS-ul) (fig. 14.38) is a motor nerve controlling tongue movements of speech, food manipulation, and swallowing. Injury to the hypoglossal nerve impairs speech and swallowing. Damage to one nerve may cause the tongue to atrophy on that side, and the tongue may deviate laterally when the subject is asked to protrude it. Damage to both nerves may render a person unable to protrude the tongue against resistance from a tongue depressor.

Cranial Nerve Learning Aid

Generations of biology and medical students have relied on mnemonic (memory-aiding) phrases and ditties, ranging from the sublimely silly to the unprintably ribald, to help them remember the cranial nerves. An old classic one often hears begins, “On old Olympus’ towering

⁶³*hypo* = below; *gloss* = tongue

FIGURE 14.37 The Accessory Nerve (XI). This nerve used to be named the *spinal accessory*, referring to its origins in the spinal cord. **APR**

FIGURE 14.38 The Hypoglossal Nerve (XII). Note how this nerve approaches the tongue from below, as its name implies.

APR

tops . . .” with the first letter of each word matching the first letter of each cranial nerve (olfactory, optic, oculomotor, etc.). Some cranial nerves have changed names, however, since that mnemonic was coined. One of the author’s former students, now a neurologist, devised the following “Old Opie” mnemonic that can remind you

of the first two to four letters (indicated in boldface) of most cranial nerve names:

Old	olfactory (I)
Opie	optic (II)
occasionally	oculomotor (III)
tries	trochlear (IV)
trigonometry	trigeminal (V)
and	abducens (VI)
feels	facial (VII)
very	vestibulocochlear (VIII)
gloomy,	glossopharyngeal (IX)
vague,	vagus (X)
and	accessory (XI)
hypoactive.	hypoglossal (XII)

Table 14.1 summarizes the cranial nerves with respect to their sensory, motor, or mixed composition, functions, origin and termination, and cranial passages (mostly foramina) through which the nerves pass on their way to or from the peripheral organs. **Figure 14.40** reviews their locations on the base of the brain and their sensory and motor connections with the peripheral organs.

DEEPER INSIGHT 14.4

CLINICAL APPLICATION

Some Cranial Nerve Disorders

*Trigeminal neuralgia*⁶⁴ (*tic douloureux*⁶⁵) is a syndrome characterized by recurring episodes of intense stabbing pain on one side of the face, often compared to an electrical shock, with painless intervals between attacks. It is usually caused by a nearby blood vessel, but sometimes a tumor, putting pressure on the trigeminal nerve. It can be triggered by touch, toothbrushing, drinking, shaving, face washing, or even a breeze on the face. The pain lasts from a few seconds to a minute or two, but may strike up to 100 times a day; it can be so unbearable that it drove some sufferers to suicide before treatments became available. It affects women more often than men, and usually strikes after age 50. It can be treated with medications; vascular surgery to relieve pressure on the nerve; or gamma knife radiosurgery, which uses targeted gamma rays to deliberately injure a small spot on the nerve and stimulate a healing process.

*Bell*⁶⁶ *palsy* is a degenerative disorder of the facial nerve, probably due to the herpesvirus that causes cold sores. It is characterized by paralysis or weakness of the facial muscles on one side with resulting distortion of the facial features, such as sagging of the mouth or eyelid. (**fig. 14.39**). The paralysis may interfere with speech, prevent closure of the eye, and sometimes inhibit tear secretion, thus causing dry eyes. There may also be a partial loss of the sense of taste. Bell palsy may appear abruptly, sometimes overnight, and often disappears spontaneously within 3 to 5 weeks.

FIGURE 14.39 Bell Palsy. Signs of damage to the right facial nerve.

⁶⁴*neur* = nerve; *algia* = pain

⁶⁵*tic* = twitch, spasm; *douloureux* = painful (French)

TABLE 14.1 The Cranial Nerves

Composition	Function	Origin	Termination	Cranial Passage
I. Olfactory Nerve				
Sensory	Smell	Olfactory mucosa in nasal cavity	Olfactory bulbs	Cribriform foramina of ethmoid bone
II. Optic Nerve				
Sensory	Vision	Retina	Thalamus and midbrain	Optic foramen
III. Oculomotor Nerve				
Motor	Eye movements, opening of eyelid, pupillary constriction, focusing	Midbrain	Somatic fibers to levator palpebrae superioris; superior, medial, and inferior rectus muscles; and inferior oblique muscle of eye. Autonomic fibers enter eyeball and lead to constrictor of iris and ciliary muscle of lens.	Superior orbital fissure
IV. Trochlear Nerve				
Motor	Eye movements	Midbrain	Superior oblique muscle of eye	Superior orbital fissure
V. Trigeminal Nerve				
Ophthalmic division (V_1)				
Sensory	Touch, temperature, and pain sensations from upper face	Superior region of face as illustrated; surface of eyeball; lacrimal (tear) gland; superior nasal mucosa; frontal and ethmoidal sinuses	Pons	Superior orbital fissure
Maxillary division (V_2)				
Sensory	Same as V_1 , lower on face	Middle region of face as illustrated; nasal mucosa; maxillary sinus; palate; upper teeth and gums	Pons	Foramen rotundum and infraorbital foramen
Mandibular division (V_3)				
Mixed	<i>Sensory:</i> Same as V_1 and V_2 , lower on face <i>Motor:</i> Mastication	<i>Sensory:</i> Inferior region of face as illustrated; anterior two-thirds of tongue (but not taste buds); lower teeth and gums; floor of mouth; dura mater <i>Motor:</i> Pons	<i>Sensory:</i> Pons <i>Motor:</i> Anterior belly of digastric; masseter, temporalis, mylohyoid, and pterygoid muscles; tensor tympani muscle of middle ear	Foramen ovale
VI. Abducens Nerve				
Motor	Lateral eye movement	Inferior pons	Lateral rectus muscle of eye	Superior orbital fissure

TABLE 14.1 The Cranial Nerves (continued)

Composition	Function	Origin	Termination	Cranial Passage
VII. Facial Nerve				
Mixed	<i>Sensory:</i> Taste <i>Motor:</i> Facial expression; secretion of tears, saliva, nasal and oral mucus	<i>Sensory:</i> Taste buds of anterior two-thirds of tongue <i>Motor:</i> Pons	<i>Sensory:</i> Thalamus <i>Motor:</i> Somatic fibers to digastric muscle, stapedius muscle of middle ear, stylohyoid muscle, muscles of facial expression. Autonomic fibers to submandibular and sublingual salivary glands, tear glands, nasal and palatine glands.	Internal acoustic meatus and stylomastoid foramen
VIII. Vestibulocochlear Nerve				
Mixed, predominantly sensory	Hearing and equilibrium	<i>Sensory:</i> Cochlea, vestibule, and semicircular ducts of inner ear <i>Motor:</i> Pons	<i>Sensory:</i> Fibers for hearing end in medulla; fibers for equilibrium end at junction of medulla and pons <i>Motor:</i> Outer hair cells of cochlea of inner ear	Internal acoustic meatus
IX. Glossopharyngeal Nerve				
Mixed	<i>Sensory:</i> Taste; touch, pressure, pain, and temperature sensations from tongue and outer ear; regulation of blood pressure and respiration <i>Motor:</i> Salivation, swallowing, gagging	<i>Sensory:</i> Pharynx; middle and outer ear; posterior one-third of tongue (including taste buds); internal carotid artery <i>Motor:</i> Medulla oblongata	<i>Sensory:</i> Medulla oblongata <i>Motor:</i> Parotid salivary gland; glands of posterior tongue; stylopharyngeal muscle (which dilates pharynx during swallowing)	Jugular foramen
X. Vagus Nerve				
Mixed	<i>Sensory:</i> Taste; sensations of hunger, fullness, and gastrointestinal discomfort <i>Motor:</i> Swallowing, speech, deceleration of heart, bronchoconstriction, gastrointestinal secretion and motility	<i>Sensory:</i> Thoracic and abdominopelvic viscera, root of tongue, pharynx, larynx, epiglottis, outer ear, dura mater <i>Motor:</i> Medulla oblongata	<i>Sensory:</i> Medulla oblongata <i>Motor:</i> Tongue, palate, pharynx, larynx, lungs, heart, liver, spleen, digestive tract, kidney, ureter	Jugular foramen
XI. Accessory Nerve				
Motor	Swallowing; head, neck, and shoulder movements	Spinal cord segments C1 to C6	Palate, pharynx, trapezius and sternocleidomastoid muscles	Jugular foramen
XII. Hypoglossal Nerve				
Motor	Tongue movements of speech, food manipulation, and swallowing	Medulla oblongata	Intrinsic and extrinsic muscles of tongue	Hypoglossal canal

FIGURE 14.40 Review of Cranial Nerve Pathways. Pathways concerned with sensory function are shown in green, and those concerned with motor function in magenta. Proprioception is omitted.

TABLE 14.2 Some Disorders Associated with the Brain and Cranial Nerves

Cerebral palsy	Muscular incoordination resulting from damage to the motor areas of the brain during fetal development, birth, or infancy; causes include prenatal rubella infection, drugs, or radiation exposure; oxygen deficiency during birth; and hydrocephalus
Concussion	Damage to the brain typically resulting from a blow, often with loss of consciousness, disturbances of vision or equilibrium, and short-term amnesia
Encephalitis	Inflammation of the brain, accompanied by fever, usually caused by mosquito-borne viruses or herpes simplex virus; causes neuronal degeneration and necrosis; can lead to delirium, seizures, and death
Epilepsy	Disorder causing sudden, massive discharge of neurons (seizures) resulting in motor convulsions, sensory and psychic disturbances, and often impaired consciousness; may result from congenital brain malformation birth trauma, later brain trauma, tumors, drug or alcohol abuse, or infections
Migraine headache	Recurring headaches often accompanied by nausea, vomiting, dizziness, and aversion to light, often triggered by such factors as weather changes, stress, hunger, red wine, or noise; more common in women and sometimes running in families
Schizophrenia	A thought disorder involving delusions, hallucinations, inappropriate emotional responses to situations, incoherent speech, and withdrawal from society, resulting from hereditary or developmental abnormalities in neural networks

You can find other brain and cranial nerve disorders described in the following places:

Hydrocephalus in Deeper Insight 8.1; *brain tumors* in Deeper Insight 12.1; *multiple sclerosis* and *Tay-Sachs disease* in Deeper Insight 12.2; *Parkinson* and *Alzheimer diseases* in Deeper Insight 12.4; *Parkinson disease*, *Huntington disease*, and *cerebellar ataxia* in section 14.5g; *meningitis* in Deeper Insight 14.1; *stroke* in Deeper Insight 14.2; *amnesia* in section 14.5d; *aprosody* and *aphasia* in section 14.5h; and *trigeminal neuralgia* and *Bell palsy* in Deeper Insight 14.4.

Like a machine with a great number of moving parts, the nervous system is highly subject to malfunctions. **Table 14.2** lists a few well-known brain and cranial nerve dysfunctions. The effects of aging on the CNS are described in chapter 29.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

25. List the purely sensory cranial nerves and state the function of each.
26. What is the only cranial nerve to extend beyond the head–neck region?
27. If the oculomotor, trochlear, or abducens nerve was damaged, the effect would be similar in all three cases. What would that effect be?
28. Which cranial nerve carries sensory signals from the greatest area of the face?
29. Name two cranial nerves involved in the sense of taste and describe where their sensory fibers originate.

DEEPER INSIGHT 14.5

CLINICAL APPLICATION

Images of the Mind

Enclosed as it is in the cranium, there is no easy way to observe a living brain directly. This has long frustrated neurobiologists, who once had to content themselves with glimpses of brain function afforded by electroencephalograms, patients with brain lesions, and patients who remained awake and conversant during brain surgery and consented to experimentation while the brain was exposed. Newer imaging methods, however, have yielded dramatic perspectives on brain function. Two of these—positron emission tomography (PET) and magnetic resonance imaging (MRI)—were explained in Deeper Insight 1.5. Both techniques rely on transient increases in blood flow to parts of the brain called into action to perform specific tasks. By monitoring these changes, neuroscientists can identify which parts of the brain are involved in specific tasks.

To produce a PET scan of the brain, the subject is given an injection of radioactively labeled glucose and a scan is made in a *control state* before any specific mental task is begun. Then the subject is given a task—for example, to read the word *car* and think of and speak a verb related to it, such as *drive*. While the subject does so, new *task-state* scans are made. Neither control- nor task-state images are very revealing by themselves, but the computer subtracts the control-state data from the task-state data and presents a color-coded image of the difference.

In such images, the busiest areas of the brain “light up” on the computer screen from moment to moment as the task is performed (fig. 14.41). This identifies the regions used for various stages of the task, such as reading the word, thinking of a verb to go with it, planning to say *drive*, and actually saying it. Among other things, such experiments demonstrate that the Broca and Wernicke areas aren’t involved in simply repeating words; they’re active, however, when a subject must evaluate a word and choose an appropriate response—that is, they function in formulating the new word the subject is going to say.

PET scans also show that different neural pools take over a task as we practice and become more proficient at it.

Functional magnetic resonance imaging (fMRI) depends on the role of astrocytes in brain metabolism. The main excitatory neurotransmitter secreted by cerebral neurons is glutamate. After a neuron releases glutamate and stimulates the next neuron, astrocytes quickly remove it from the synapse and convert it to glutamine. They acquire the energy for this from the anaerobic fermentation of glucose. High activity in an area of cortex thus requires an increased blood flow to supply this glucose, but it doesn’t elevate oxygen consumption from that blood. Thus, the oxygen supply exceeds demand in that part of the brain, and blood leaving the region contains more oxygen than the blood leaving less active regions. Since the magnetic properties of hemoglobin depend on how much oxygen is bound to it, fMRI can detect changes in brain circulation.

fMRI is more precise than PET and pinpoints regions of brain activity with a precision of 1 to 2 mm. It also has the advantages of requiring no injected substances and no exposure to radioisotopes. While it takes about 1 minute to produce a PET scan, fMRI produces images much more quickly, which makes it more useful for determining how the brain responds immediately to sensory input or mental tasks.

Cutting-edge advances in PET and fMRI technology have enhanced our knowledge of shifting patterns of brain activity associated with attention and consciousness, sensory perception, memory, emotion, motor control, reading, speaking, musical judgment, planning a chess strategy, and so forth. In addition to their contribution to basic neuroscience, these techniques are highly valuable to neurosurgery and psychopharmacology. They have enhanced our understanding of dysfunctions such as depression, schizophrenia, and attention-deficit/hyperactivity disorder (ADHD). Such methods ushered in an exciting era of safe visualization of brain function, producing pictures of the mind at work.

FIGURE 14.41 PET Scans of the Brain Made During the Performance of a Language Task. These images show the cortical regions that are active when a person reads words and then speaks them. The most active areas are shown in red and less active areas in blue.

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

14.1 Overview of the Brain

1. Typical mass of the adult brain
2. Meanings of the directional terms *rostral* and *caudal* in brain anatomy
3. Three principal divisions of the brain
4. Names of the tissue folds and shallow grooves in the cerebrum and cerebellum, and the names of the deep grooves between the two cerebral hemispheres and between the cerebrum and cerebellum
5. Locations of the gray and white matter in the cerebrum and cerebellum; the composition of gray and white matter and how this relates to their colors; and the meaning of *cortex*, *nucleus*, and *tract* in relation to brain gray and white matter
6. Embryonic development of the brain from neural plate to neural tube stage; differentiation into forebrain, midbrain, and hindbrain; development of the five embryonic brain vesicles; and the name and destiny of each vesicle

14.2 Meninges, Ventricles, Cerebrospinal Fluid, and Blood Supply

1. The three meninges of the brain; two subdivisions of the dura mater; and the relationship of the dural sinuses and subarachnoid space to the meninges
2. Ventricles of the brain, their names and locations, and the passages that connect them
3. The relationship of the ependymal cells and choroid plexuses to the brain ventricles and canals
4. The sources, flow, reabsorption, and functions of the cerebrospinal fluid (CSF)
5. The brain's demands for blood flow, glucose, and oxygen in relation to its percentage of the body weight
6. Structure and function of the blood–brain and blood–CSF barriers, and the clinical relevance of the brain barrier system
7. The locations, structural nature, function, and clinical relevance of circumventricular organs

14.3 The Hindbrain and Midbrain

1. The medulla oblongata: its location, gross anatomy, and general functions; which cranial nerves arise from it; and the specific functions of each of its tracts and nuclei
2. The pons: its location, gross anatomy, and functions; which cranial nerves arise from the pons and from the groove between pons and medulla; and its contributions to the anterolateral system and anterior spino-cerebellar tract
3. The midbrain: its location, gross anatomy, and general functions; which cranial nerves arise from it; and the specific functions of its colliculi, substantia nigra, and central gray substance
4. How the reticular formation relates to the foregoing brainstem regions in location, structure, and functions
5. The cerebellum: its location, gross anatomy, unique neuron types, its three pairs of peduncles, and their relationship to cerebellar input and output
6. The classical view of cerebellar function and how this has lately expanded as a result of brain imaging studies and studies of people with cerebellar lesions

14.4 The Forebrain

1. The two major parts of the forebrain
2. Three principal parts of the diencephalon
3. Thalamic functions, location, and gross anatomy
4. Hypothalamic functions, location, gross anatomy, and anatomical and physiological relationships with the pituitary gland
5. The location, components, and functions of the epithalamus
6. Gross anatomy of the cerebral hemispheres, their five lobes, and the functions of each lobe
7. Three types of cerebral tracts and their defining anatomical and functional differences
8. Three locations of cerebral gray matter
9. The thickness, extent, and relative amount of tissue and number of neurons in the cerebral cortex
10. Two types of neurons in the cerebral cortex and their morphology
11. Evolutionary and structural distinctions between archicortex, paleocortex, and

neocortex, and where each occurs in the human brain

12. The location, constituents, and functions of the limbic system
13. Names, locations, and functions of the basal nuclei

14.5 Integrative Functions of the Brain

1. Four kinds of brain waves in the EEG, the states in which each type normally dominates the EEG, and the clinical relevance of the EEG
2. Stages of sleep; physiological characteristics of each; roles of the hypothalamus, reticular formation, melatonin, and orexins in regulating the sleep cycle; and theories on the functions of sleep
3. Association areas of the cerebral cortex; the involvement of some of these in cognitive function; and the contributions of brain injury patients and brain imaging methods to understanding the regional distribution of cognitive functions
4. Brain regions involved in memory; forms of amnesia
5. Brain regions involved in emotion, and insights into the neurobiology of emotion from brain trauma, ablation, and brain stimulation studies
6. Brain regions involved in the special and general senses
7. The functional relationship between primary sensory cortex and sensory association areas
8. Location of the postcentral gyrus; its somatosensory function; its somatotopy as charted in the sensory homunculus; and the effect of decussation on its function
9. Locations of the precentral gyrus and motor association area; their roles in motor control; the somatotopy of the gyrus as charted in the motor homunculus; and the effect of decussation on its function
10. Upper and lower motor neurons and the course of their axons
11. Roles of the basal nuclei and cerebellum in motor coordination and learned motor skills
12. Effects of Parkinson disease and basal nuclei lesions on motor control
13. Locations of the Wernicke and Broca areas; their roles in language; interaction of the Broca area and precentral gyrus in speech;

STUDY GUIDE

and forms of aphasia and other language deficits resulting from damage to the language centers

14. Cerebral lateralization; functional differences between the categorical and representational hemispheres; and why it cannot be said that a particular function is necessarily “right-brained” or “left-brained”

14.6 The Cranial Nerves

- Names and numbers of the 12 pairs of cranial nerves, and their relationships to the brainstem and skull foramina
- Which cranial nerves are purely sensory, which are mixed, which have traditionally been regarded as motor, and why it is not

entirely accurate to simply call them motor nerves

- For each cranial nerve, its location, functions, origin, termination, and passage through the skull
- Signs of damage to each cranial nerve, and clinical methods of testing for damage

▶ Testing Your Recall

Answers in Appendix A

- Which of these is caudal to the hypothalamus?
 - the thalamus
 - the optic chiasm
 - the cerebral aqueduct
 - the pituitary gland
 - the corpus callosum
- If the telencephalon was removed from a 5-week-old embryo, which of the following structures would fail to develop in the fetus?
 - cerebral hemispheres
 - the thalamus
 - the midbrain
 - the medulla oblongata
 - the spinal cord
- The blood–CSF barrier is formed by
 - blood capillaries.
 - endothelial cells.
 - protoplasmic astrocytes.
 - oligodendrocytes.
 - ependymal cells.
- The pyramids of the medulla oblongata contain
 - descending corticospinal fibers.
 - commissural fibers.
 - ascending spinocerebellar fibers.
 - fibers going to and from the cerebellum.
 - ascending spinothalamic fibers.
- Which of the following does *not* receive any input from the eyes?
 - the hypothalamus
 - the frontal lobe
 - the thalamus
 - the occipital lobe
 - the midbrain
- While studying in a noisy cafeteria, you get sleepy and doze off for a few minutes. You awaken with a start and realize that all

the cafeteria sounds have just “come back.” While you were dozing, this auditory input was blocked from reaching your auditory cortex by

- the temporal lobe.
 - the hypothalamus.
 - the reticular activating system.
 - the medulla oblongata.
 - the vestibulocochlear nerve.
- Because of a brain lesion, a certain patient never feels full, but eats so excessively as to now weigh nearly 270 kg (600 lb). The lesion is most likely in the patient’s
 - hypothalamus.
 - amygdala.
 - hippocampus.
 - basal nuclei.
 - pons.
 - The _____ is most closely associated with the cerebellum in embryonic development and remains its primary source of input fibers throughout life.
 - telencephalon
 - thalamus
 - midbrain
 - pons
 - medulla
 - Damage to the _____ nerve could result in defects of eye movement.
 - optic
 - vagus
 - trigeminal
 - facial
 - abducens
 - All of the following *except* the _____ nerve begin or end in the orbit.
 - optic
 - oculomotor

- trochlear
- abducens
- accessory

- The right and left cerebral hemispheres are connected to each other by a thick C-shaped bundle of fibers called the _____.
- The brain has four chambers called _____ filled with _____ fluid.
- On a sagittal plane, the cerebellar white matter exhibits a branching pattern called the _____.
- The only cranial nerve with direct control over the lower digestive tract is the _____.
- Cerebrospinal fluid is secreted partly by a mass of blood capillaries called the _____ in each ventricle.
- The primary motor area of the cerebrum is the _____ gyrus of the frontal lobe.
- A lesion in which lobe of the cerebrum is most likely to cause a radical alteration of the personality?
- Areas of cerebral cortex that identify or interpret sensory information are called _____.
- Linear, analytical, and verbal thinking occurs in the _____ hemisphere of the cerebrum, which is on the left in most people.
- The cranial nerve that controls most facial expression is the _____, whereas the one through which a person feels most facial sensation is the _____.

STUDY GUIDE

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|-------------|---------------|-------------|
| 1. -algia | 3. cerebro- | 7. insulo- |
| 2. cephalo- | 4. corpo- | 8. oculo- |

DEEPER INSIGHTS

- 15.1** Clinical Application: Megacolon
- 15.2** Clinical Application: Drugs and the Nervous System

BRUSHING UP

- The function of the autonomic nervous system is heavily grounded in the concepts of negative feedback and homeostasis (see section 1.6c).
- Figure 12.2 provides a helpful perspective on how the autonomic nervous system (ANS) fits into the scheme of the nervous system as a whole.
- It is important that you clearly understand neurotransmitters and receptors and why neurotransmitters can have either excitatory or inhibitory effects on different target cells (see sections 12.5c, 12.5d).
- Many effects of the ANS are carried out by smooth muscle. The innervation of smooth muscle will help in understanding the effects described in this chapter (see section 11.7b).
- You should be familiar with the anatomy and functions of the hypothalamus, a highly important autonomic integrating center (see section 14.4a).
- Autonomic signals travel to their target organs by way of the spinal nerves described in section 13.2b and cranial nerves III, VII, IX, and X, detailed in section 14.6c.

We are consciously aware of many of the activities of our nervous system discussed in the preceding chapters—the general and special senses, our thought processes and emotions, and our voluntary movements. But there is another branch of the nervous system that operates in comparative secrecy, usually without our willing it, thinking about it, or even being able to consciously modify or suppress it.

This secretive agent is called the *autonomic nervous system* (ANS). Its name means “self-governed,” as it is almost fully independent of our will. Its job is to regulate such fundamental states and life processes as heart rate, blood pressure, body temperature, respiratory airflow, pupillary diameter, digestion, energy metabolism, defecation, urination, and sexual functions. In short, the ANS quietly manages a multitude of involuntary processes responsible for the body’s homeostasis.

Walter Cannon (1871–1945), the American physiologist who coined such expressions as *homeostasis* and the *fight-or-flight reaction*, dedicated his career to the study of the autonomic nervous system. He found that an animal can live without a functional sympathetic nervous system (one of the two divisions of the ANS), but it must be kept warm and free of stress. It can’t regulate its body temperature, tolerate any strenuous exertion, or survive on its own. Indeed, the ANS is more necessary for survival than are many functions of the somatic nervous system; an absence of autonomic function is fatal because the body can’t maintain homeostasis without it. Thus, for an understanding of bodily function, the mode of action of many drugs, and other aspects of health care, we must be especially aware of how the ANS works.

15.1 General Properties of the Autonomic Nervous System

Expected Learning Outcomes

When you have completed this section, you should be able to

- explain how the autonomic and somatic nervous systems differ in form and function; and
- explain how the two divisions of the autonomic nervous system differ in general function.

The **autonomic¹ nervous system (ANS)** can be narrowly defined as a motor nervous system that controls glands, cardiac muscle, and smooth muscle. It is also called the **visceral motor system** to distinguish it from the somatic motor system that controls the skeletal muscles. The primary target organs of the ANS are viscera of the thoracic and abdominopelvic cavities and some structures of the body wall, including cutaneous blood vessels, sweat glands, and arrector muscles of the hairs.

The ANS usually carries out its actions involuntarily, without one’s intent or awareness, in contrast to the voluntary nature of the somatic motor system. This voluntary–involuntary distinction is not, however, as clear-cut as it may seem. Some skeletal muscle responses are quite involuntary, such as the somatic reflexes, and some muscles are difficult or impossible to control, such as the middle-ear muscles. On the other hand, therapeutic uses of biofeedback have shown that some people can learn to voluntarily control such autonomic, visceral functions as blood pressure and heart rate.

Visceral effectors don’t depend on the autonomic nervous system to function, but only to adjust their activity to the body’s changing needs. The heart, for example, goes on beating even if all the nerves to it are severed, but the ANS normally modulates the heart rate in conditions of rest or exercise. If the somatic nerves to a skeletal muscle are severed, the muscle exhibits flaccid paralysis—it no longer functions. But if the autonomic nerves to cardiac or smooth muscle are severed, the muscle exhibits exaggerated responses (*denervation hypersensitivity*).

15.1a Visceral Reflexes

The ANS is responsible for the body’s **visceral² reflexes**—unconscious, automatic, stereotyped responses to stimulation, much like the somatic reflexes discussed in chapter 13, but involving visceral receptors and effectors and slower responses. Some authorities regard the visceral afferent (sensory) pathways as part of the ANS, but most prefer to limit the term *ANS* to the efferent (motor) pathways. Regardless of this preference, however, autonomic activity involves a visceral reflex arc that includes (1) **receptors** (nerve endings that detect stretch, tissue damage, blood chemistry, body

¹*auto* = self; *nom* = rule (self-governed)

²*viscero* = internal organs

FIGURE 15.1 An Autonomic Reflex Arc. This pathway produces the baroreflex, which compensates for blood pressure fluctuations in arteries above the heart.

temperature, and other internal stimuli), (2) **afferent neurons** leading to (3) an **integrating center** and interneurons in the CNS, (4) **efferent neurons** carrying motor signals away from the CNS, and finally (5) an **effector** that carries out the end response.

For example, high blood pressure activates a visceral *baroreflex*.³ It stimulates stretch receptors called *baroreceptors* in the internal carotid arteries and they send signals via the glossopharyngeal nerves to the brainstem (fig. 15.1). The medulla integrates this with other information and sends signals back to the heart by way of the vagus nerves. The vagus nerves slow down the heart and reduce blood pressure, thus completing a homeostatic negative feedback loop. A separate autonomic reflex accelerates the heart when blood pressure drops below normal—for example, when we move from a reclining to a standing position and gravity draws blood away from the upper body (see fig. 1.8).

³baro = pressure

15.1b Divisions of the Autonomic Nervous System

The ANS has three subsystems: the sympathetic and parasympathetic divisions and the enteric plexus (see fig. 12.2). They differ in anatomy and function, but often innervate the same target organs and may have cooperative or contrasting effects on them.

The **sympathetic division** adapts the body in many ways for physical activity—it increases alertness, heart rate, blood pressure, pulmonary airflow, blood glucose, and blood flow to cardiac and skeletal muscle, but at the same time, it reduces blood flow to the skin and digestive tract. Cannon referred to extreme sympathetic responses as the *fight-or-flight reaction* because it comes into play when an animal must attack, defend itself, or flee from danger. In our own lives, this reaction occurs in situations involving arousal, exercise, competition, stress, danger, trauma, anger, or fear. Ordinarily, however, the sympathetic division has more subtle effects that we notice barely, if at all.

The **parasympathetic division**, by comparison, has a calming effect on many body functions. It is associated with reduced energy expenditure and normal bodily maintenance, including such functions as digestion and waste elimination. This is often called the *resting-and-digesting state*.

This doesn't mean that the body alternates between states where one system or the other is active. Normally, both systems are active simultaneously. They exhibit a background rate of activity called **autonomic tone**, and the balance between *sympathetic tone* and *parasympathetic tone* shifts in accordance with the body's changing needs. Parasympathetic tone, for example, maintains smooth muscle tone in the intestines and holds the resting heart rate down to about 70 to 80 beats/min. Sympathetic tone keeps most blood vessels partially constricted and thus maintains blood pressure. A loss of sympathetic tone can cause such a rapid drop in blood pressure that a person goes into shock and may faint.

The **enteric plexus** is a complex network of autonomic neurons in the wall of the digestive tract. It employs neural pathways and neurotransmitters much different from the sympathetic and parasympathetic divisions. We will explore it later in this chapter and chapter 25, but most of this chapter concerns the sympathetic and parasympathetic divisions.

15.1c Autonomic Output Pathways

Although usually defined only as part of the peripheral nervous system, the ANS has components in both the CNS and PNS. It includes control nuclei in the hypothalamus and other regions of the brainstem, motor neurons in the spinal cord and peripheral ganglia, and nerve fibers that travel through the cranial and spinal nerves you have already studied.

The autonomic motor pathway to a target organ differs significantly from somatic motor pathways (fig. 15.2; table 15.1). In somatic pathways, a motor neuron in the brainstem or spinal cord issues a myelinated fiber (axon) that reaches all the way to a skeletal muscle. In autonomic pathways, the signal travels across *two* neurons to get to the target organ, and it must cross a synapse where these two neurons meet in an autonomic ganglion. The axon of the first neuron in the pathway is called the **preganglionic fiber**.

FIGURE 15.2 Comparison of Somatic and Autonomic Efferent Pathways. (a) In the somatic nervous system, each motor nerve fiber extends all the way from the CNS to a skeletal muscle. (b) In the sympathetic nervous system, a short preganglionic fiber extends from the spinal cord to a sympathetic ganglion usually near the vertebral column. A longer postganglionic fiber extends from there to the target organ. (c) In the parasympathetic nervous system, a long preganglionic fiber extends from the CNS to a ganglion in or near the target organ, and a short postganglionic fiber completes the path to specific effector cells in that organ (smooth or cardiac muscle or glands). (ACh = acetylcholine; NE = norepinephrine)

It begins with a cell body in the brainstem or spinal cord. Its axon extends from there to an autonomic ganglion somewhere outside the CNS—often in a chain near the vertebral column or located in or near the target organ. Here, it synapses with the second neuron and secretes the neurotransmitter acetylcholine (ACh). The axon from the second neuron, called the **postganglionic fiber**, leaves the ganglion and extends the rest of the way to the target organ or cells. Depending on the fiber type, it secretes either ACh or norepinephrine (NE). Autonomic preganglionic fibers are lightly myelinated and the postganglionic fibers are unmyelinated. In contrast to somatic motor nerve endings, autonomic postganglionic fibers don't end in one-to-one synapses with muscle cells, but in chains of beadlike varicosities that diffusely release neurotransmitter into

the tissue and stimulate many target cells at once (see section 11.7b and fig. 11.21). Figure 15.2 shows key differences between the somatic and autonomic pathways and between the sympathetic and parasympathetic divisions.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

1. How does the autonomic nervous system differ functionally and anatomically from the somatic motor system?
2. How do the general effects of the sympathetic division differ from those of the parasympathetic division?

TABLE 15.1 Comparison of the Somatic and Autonomic Nervous Systems		
Feature	Somatic	Autonomic
Effectors	Skeletal muscle	Glands, smooth muscle, cardiac muscle
Control	Usually voluntary	Usually involuntary
Distal nerve endings	Neuromuscular junctions	Usually varicosities
Efferent pathways	One nerve fiber from CNS to effector; no ganglia	Two nerve fibers from CNS to effector; synapse at a ganglion
Neurotransmitters	Acetylcholine (ACh)	ACh and norepinephrine (NE)
Effect on target cells	Always excitatory	Excitatory or inhibitory
Effect of denervation	Flaccid paralysis	Denervation hypersensitivity

15.2 Anatomy of the Autonomic Nervous System

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. identify the anatomical components and nerve pathways of the sympathetic and parasympathetic divisions;
- b. discuss the relationship of the adrenal glands to the sympathetic nervous system; and
- c. describe the enteric plexus of the digestive tract and explain its significance.

15.2a The Sympathetic Division

All pathways of the sympathetic division begin in the thoracic and lumbar regions of the spinal cord; hence, this system is also called the *thoracolumbar division*. The cell bodies of its preganglionic neurons are in the lateral horns and nearby gray matter of the spinal cord. Their axons exit the cord by way of spinal nerves T1 to L2 and lead to the nearby **sympathetic chain** of ganglia (**paravertebral⁴ ganglia**). Thus, the sympathetic division has relatively short preganglionic axons. The sympathetic chain is a longitudinal series of ganglia that lie adjacent to both sides of the vertebral column from the cervical to the coccygeal level. They are interconnected by longitudinal nerve cords (**figs. 15.3, 15.4**;

⁴para = next to; vertebr = vertebral column

FIGURE 15.3 The Sympathetic Chain Ganglia. Right lateral view of the thoracic cavity of a cadaver. (n. = nerve) **APR**

FIGURE 15.4 Schematic of the Sympathetic Nervous System. APR

? Does the sympathetic innervation of the lungs make a person inhale and exhale? Explain.

FIGURE 15.5 Neural Pathways Through the Sympathetic Chain Ganglia. Sympathetic fibers can follow any of the three numbered routes: (1) the spinal nerve route, (2) the sympathetic nerve route, or (3) the splanchnic nerve route. The somatic efferent pathway is shown on the left for comparison.

? Name the parts of the spinal cord where the cell bodies of the sympathetic and somatic efferent neurons are located.

see also fig. 13.14 for the relationship of this chain to the spinal nerves and vertebrae). The number of ganglia in this chain varies from person to person, but usually there are 3 cervical (*superior*, *middle*, and *inferior*), 11 thoracic, 4 lumbar, 4 sacral, and 1 coccygeal ganglion in each chain.

It may seem odd that sympathetic ganglia exist in the cervical, sacral, and coccygeal regions considering that sympathetic neurons originate only in the thoracic and lumbar regions of the spinal cord (levels T1 to L2). But as shown in figure 15.4, nerve cords from the thoracic region ascend to the ganglia in the neck, and cords from the lumbar region descend to the sacral and coccygeal ganglia. Consequently, sympathetic nerve fibers are distributed to every level of the body. As a general rule, the head receives sympathetic output arising from spinal cord segment T1, the neck from T2, the thorax and upper limbs from T3 to T6, the abdomen from T7 to T11, and the lower limbs from T12 to L2. There is considerable overlap and individual variation in this pattern, however.

In the thoracolumbar region, each paravertebral ganglion is connected to a spinal nerve by two branches called *communicating*

rami (fig. 15.5). The preganglionic neurons have cell bodies in the lateral horn of the spinal cord. Their axons, in the small myelinated class of nerve fibers, pass out the ventral root, travel a short distance in the spinal nerve, then leave the nerve and travel to the sympathetic ganglion by way of the **white communicating ramus**.⁵ This ramus is named for the color imparted by its myelin. Unmyelinated postganglionic fibers leave the ganglion by way of the **gray communicating ramus**, named for its lack of myelin and duller color, and by other routes. This ramus returns to the spinal nerve. Postganglionic fibers, longer than the preganglionics, extend the rest of the way to the target organ.

▶▶▶ APPLY WHAT YOU KNOW

Would autonomic postganglionic fibers have faster or slower conduction speeds than somatic motor fibers? Why? (See hints in section 12.3d.)

⁵ramus = branch

TABLE 15.2 Innervation to and from the Collateral Ganglia

Sympathetic Ganglia	→	Collateral Ganglia	→	Postganglionic Target Organs
Thoracic ganglion 5 to 9 or 10	→	Celiac ganglion	→	Stomach, spleen, liver, pancreas, small intestine, and kidneys
Thoracic ganglia 9 to 12	→	Celiac and superior mesenteric ganglia	→	Small intestine, colon, and kidneys
Lumbar ganglia	→	Inferior mesenteric ganglion	→	Rectum, urinary bladder, and reproductive organs

After entering the sympathetic chain, preganglionic fibers may follow any of three courses:

- Some end in the ganglion they enter and synapse immediately with a postganglionic neuron.
- Some travel up or down the chain and synapse in ganglia at other levels. It is these fibers that link the paravertebral ganglia into a chain. They are the only route by which ganglia at the cervical, sacral, and coccygeal levels receive input.
- Some pass through the chain without synapsing and continue as *splanchnic nerves*, to be considered shortly.

Nerve fibers leave the sympathetic chain by three routes. These are numbered in figure 15.5 to correspond to the following descriptions:

- 1 The spinal nerve route.** Some postganglionic fibers exit a ganglion by way of the gray ramus, return to the spinal nerve or its subdivisions, and travel the rest of the way to the target organ. This is the route to most sweat glands, arrector muscles, and blood vessels of the skin and skeletal muscles.
- 2 The sympathetic nerve route.** Other postganglionic fibers leave by way of sympathetic nerves that extend to the heart, lungs, esophagus, and thoracic blood vessels. These nerves form a **carotid plexus** around each carotid artery of the neck and issue fibers from there to effectors in the head—including sweat, salivary, and nasal glands; arrector muscles; blood vessels; and dilators of the iris. Some fibers from the superior and middle cervical ganglia form the *cardiac nerves* to the heart (which also contain parasympathetic fibers).
- 3 The splanchnic⁶ nerve route.** Some of the fibers that arise from spinal nerves T5 to T12 pass through the sympathetic ganglia without synapsing. Beyond the ganglia, they travel in the **splanchnic nerves** (SPLANK-nic), which lead to a second set of ganglia called **collateral ganglia**. Here the preganglionic fibers synapse with the postganglionic neurons.

The collateral ganglia contribute to a network called the **abdominal aortic plexus** wrapped around the aorta (**fig. 15.6**).

There are three major collateral ganglia in this plexus—the **celiac**, **superior mesenteric**, and **inferior mesenteric ganglia**—located at points where arteries of the same names branch off the aorta. The postganglionic fibers accompany these arteries and their branches to the target organs. **Table 15.2** summarizes the innervation to and from the three major collateral ganglia.

The term *solar plexus* is used by some authorities as a collective name for the celiac and superior mesenteric ganglia, and by others as a synonym for the celiac ganglion only. The term comes from the nerves radiating from the ganglion like rays of the sun.

In summary, effectors in the muscles and body wall are innervated mainly by sympathetic fibers in the spinal nerves, effectors in the head and thoracic cavity by sympathetic nerves, and effectors in the abdominopelvic cavity by splanchnic nerves.

There is no simple one-to-one relationship between preganglionic and postganglionic neurons in the sympathetic division. For one thing, each postganglionic neuron may receive synapses from multiple preganglionic neurons, thus exhibiting the principle of *neural convergence*. Furthermore, each preganglionic neuron branches out to multiple postganglionic neurons, thus showing *neural divergence*. (See section 12.6d to review diverging and converging circuits.) Most sympathetic preganglionic neurons synapse with 10 to 20 postganglionic neurons. Therefore, when one preganglionic neuron fires, it can excite multiple postganglionic neurons leading to different target organs. The sympathetic division thus tends to have relatively widespread effects—as suggested by the name *sympathetic*.⁷

15.2b The Adrenal Glands

The paired **adrenal⁸ (suprarenal) glands** rest like hats on the superior poles of the kidneys (**fig. 15.6**). Each adrenal is actually two glands with different functions and embryonic origins. The outer rind, the **adrenal cortex**, secretes steroid hormones discussed in chapter 17. The inner core, the **adrenal medulla**, is essentially a sympathetic ganglion. It consists of modified postganglionic neurons without dendrites or axons. Sympathetic preganglionic fibers penetrate through the cortex and terminate on these cells. The sympathetic nervous system and adrenal medulla are so closely related in development and function that they are referred to collectively as the *sympathoadrenal system*.

⁶splanchn = viscera

⁷sym = together; path = feeling

⁸ad = near; ren = kidney

FIGURE 15.6 Abdominopelvic Components of the Sympathoadrenal System. (a) Collateral ganglia, abdominal aortic plexus, and adrenal glands. (b) The adrenal gland, frontal section. Only the adrenal medulla plays a role in the sympathetic nervous system; the adrenal cortex has unrelated roles described in chapter 17.

When stimulated, the adrenal medulla secretes a mixture of hormones into the bloodstream—about 85% epinephrine (adrenaline), 15% norepinephrine (noradrenaline), and a trace of dopamine. These hormones, the *catecholamines*, were briefly considered in chapter 12 because they also function as neurotransmitters.

15.2c The Parasympathetic Division

The parasympathetic division is also called the *craniosacral division* because its signaling pathways begin in the brain and sacral region of the spinal cord; they travel in certain cranial and sacral nerves. Cell bodies of the preganglionic neurons are located in the midbrain, pons, medulla oblongata, and segments S2 to S4 of the spinal cord (**fig. 15.7**). They issue long preganglionic fibers that end in **terminal ganglia** in or near the target organ. (If a terminal

ganglion is embedded in the wall of a target organ, it is also called an *intramural*⁹ ganglion.) Thus, the parasympathetic division has long preganglionic fibers, reaching almost all the way to the target cells, and short postganglionic fibers that cover the rest of the distance.

There is some neural divergence in the parasympathetic division, but much less than in the sympathetic. The parasympathetic division has a ratio of fewer than five postganglionic neurons to every preganglionic neuron. Furthermore, the preganglionic fibers reach their target organs before even this slight divergence occurs. The parasympathetic division is therefore relatively selective in its stimulation of target organs.

⁹*intra* = within; *mur* = wall

FIGURE 15.7 Schematic of the Parasympathetic Nervous System. **APR**

? Which nerve carries the most parasympathetic nerve fibers?

Parasympathetic fibers leave the brainstem in the following cranial nerves (CNs). The first three supply all parasympathetic innervation to the head, and the last one supplies viscera of the thoracic and abdominopelvic cavities.

1. **Oculomotor nerve (CN III)** (see fig. 14.29). The oculomotor nerve carries parasympathetic fibers that control the lens and pupil of the eye. The preganglionic fibers enter the orbit and terminate in the *ciliary ganglion* behind the eyeball. Postganglionic fibers enter the eyeball and innervate the *ciliary muscle*, which thickens the lens, and the *pupillary constrictor*, which narrows the pupil.
2. **Facial nerve (CN VII)** (see fig. 14.33). The facial nerve carries parasympathetic fibers that regulate the tear glands, salivary glands, and nasal glands. Soon after the facial nerve emerges from the pons, its parasympathetic fibers split away and form two smaller branches. The superior branch ends at the *pterygopalatine ganglion* near the junction of the maxilla and palatine bone. Postganglionic fibers then continue to the tear glands and glands of the nasal cavity, palate, and other areas of the oral cavity. The inferior branch crosses the middle-ear cavity and ends at the *submandibular ganglion* near the angle of the mandible. Postganglionic fibers from here supply salivary glands in the floor of the mouth.
3. **Glossopharyngeal nerve (CN IX)** (see fig. 14.35). The glossopharyngeal nerve also carries parasympathetic fibers concerned with salivation. The preganglionic fibers leave this nerve soon after its origin and form the *tympanic nerve*. This nerve crosses the middle-ear cavity and ends in the *otic*¹⁰ *ganglion* near the foramen ovale. The postganglionic fibers then follow the trigeminal nerve to the *parotid salivary gland* just in front of the earlobe.
4. **Vagus nerve (CN X)** (see fig. 14.36). The vagus nerve carries about 90% of all parasympathetic preganglionic fibers. It travels down the neck and forms three networks in the mediastinum of the chest—the **cardiac plexus**, which supplies fibers to the heart; the **pulmonary plexus**, whose fibers accompany the bronchi and blood vessels into the lungs; and the **esophageal plexus**, whose fibers regulate swallowing.

¹⁰*ot* = ear; *ic* = pertaining to

At the lower end of the esophagus, these plexuses give off anterior and posterior **vagal trunks**, each of which contains fibers from both the right and left vagus nerves. These trunks penetrate the diaphragm, enter the abdominal cavity, and contribute to the extensive *abdominal aortic plexus* mentioned earlier. As we have seen, sympathetic fibers synapse here. The parasympathetic fibers, however, pass through the plexus without synapsing. They synapse farther along, in terminal ganglia in or near the liver, pancreas, stomach, small intestine, kidney, ureter, and proximal half of the colon.

The remaining parasympathetic fibers arise from levels S2 to S4 of the lower spinal cord. They travel a short distance in the anterior rami of the spinal nerves and then form **pelvic splanchnic nerves** that lead to the **inferior hypogastric plexus**. Some parasympathetic fibers synapse here, but most pass through this plexus and travel by way of **pelvic nerves** to the terminal ganglia in their target organs: the distal half of the colon, the rectum, urinary bladder, and reproductive organs. With few exceptions, the parasympathetic system doesn't innervate body wall structures (sweat glands, arrector muscles, or cutaneous blood vessels).

The sympathetic and parasympathetic divisions of the ANS are compared in **table 15.3**.

▶▶▶ **APPLY WHAT YOU KNOW**

Would autonomic functions be affected if the anterior roots of the cervical spinal nerves were damaged? Why or why not?

15.2d The Enteric Plexus

The digestive tract has an extensive nervous network of its own called the **enteric**¹¹ **plexus (enteric nervous system)** (see fig. 12.2). Some consider it part of the parasympathetic division, but it has a complex neural circuitry unlike any of the rest of the autonomic nervous system, and uses different transmitters. It seems best regarded as a third autonomic division. It consists of about 500 million neurons of 20 functional classes—five times as many neurons as the spinal cord!—and has its own ganglia and reflex arcs. Unlike the rest of the autonomic nervous system, it doesn't arise from the brainstem or spinal cord, but like the rest, it innervates smooth muscle and glands.

¹¹*enter* = intestines; *ic* = pertaining to

TABLE 15.3 Comparison of the Sympathetic and Parasympathetic Divisions		
Feature	Sympathetic	Parasympathetic
Origin in CNS	Thoracolumbar	Craniosacral
Location of ganglia	Paravertebral ganglia adjacent to spinal column and prevertebral ganglia anterior to it	Terminal ganglia near or within target organs
Fiber lengths	Short preganglionic	Long preganglionic
	Long postganglionic	Short postganglionic
Neural divergence	Extensive	Minimal
Effects of system	Often widespread and general	More specific and local

The enteric plexus regulates the motility of the esophagus, stomach, and intestines and the secretion of digestive enzymes and acid. To function normally, however, these digestive activities also require regulation by the sympathetic and parasympathetic systems. The enteric plexus is discussed in more detail in chapter 25. Its importance in intestinal motility becomes dramatically apparent when the plexus is absent (see Deeper Insight 15.1).

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

3. Explain why the sympathetic division is also called the thoracolumbar division even though its paravertebral ganglia extend all the way from the cervical to the sacral region.
4. Describe or diagram the structural relationships among the following: preganglionic fiber, postganglionic fiber, gray ramus, white ramus, and sympathetic ganglion.
5. Explain in anatomical terms why the parasympathetic division affects target organs more selectively than the sympathetic division does.
6. Trace the pathway of a parasympathetic fiber of the vagus nerve from the medulla oblongata to the small intestine.

DEEPER INSIGHT 15.1 CLINICAL APPLICATION

Megacolon

The importance of the enteric plexus becomes vividly clear when it's absent. Such is the case in a hereditary defect called *Hirschsprung*¹² disease. During normal embryonic development, neural crest cells migrate to the large intestine and establish the enteric plexus. In Hirschsprung disease, however, they fail to supply the distal parts of the large intestine, leaving the sigmoid colon and rectum (see fig. 25.33) without enteric ganglia. In the absence of these ganglia, the sigmoidorectal region lacks motility, constricts permanently, and obstructs the passage of feces. Feces accumulate and become impacted above the constriction, resulting in *megacolon*—a massive dilation of the bowel accompanied by abdominal distension and chronic constipation. The most life-threatening complications are colonic gangrene, perforation of the bowel, and bacterial infection of the peritoneum (*peritonitis*). The treatment of choice is surgical removal of the affected segment and attachment of the healthy colon directly to the anal canal.

Hirschsprung disease is usually evident even in the newborn, which fails to have its first expected bowel movement. It affects four times as many infant boys as girls, and although its incidence in the general population is about 1 in 5,000 live births, it occurs in about 1 out of 10 infants with Down syndrome.

Hirschsprung disease isn't the only cause of megacolon. In Central and South America, biting insects called *kissing bugs* transmit parasites called *trypanosomes* to humans. These parasites, similar to the ones that cause African sleeping sickness, cause *Chagas*¹³ disease. Among other effects, they destroy the ganglia of the enteric plexus, leading to a massively enlarged and often gangrenous colon.

¹³Carlos Chagas (1879–1934), Brazilian physician

15.3 Autonomic Effects on Target Organs

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. name the neurotransmitters employed at different synapses of the ANS;
- b. name the receptors for these neurotransmitters and explain how they relate to autonomic effects;
- c. explain how the ANS controls many target organs through dual innervation; and
- d. explain how control is exerted in the absence of dual innervation.

15.3a Neurotransmitters and Their Receptors

As noted earlier, the divisions of the ANS often have contrasting effects on an organ. The sympathetic division accelerates the heartbeat and the parasympathetic division slows it down, for example. But each division of the ANS also can have contrasting effects on different organs. For example, the parasympathetic division contracts the wall of the urinary bladder but relaxes the male internal urethral sphincter; both actions are necessary for the expulsion of urine. It employs acetylcholine for both purposes. Similarly, the sympathetic division constricts most blood vessels but dilates the bronchioles of the lungs, and it achieves both effects with norepinephrine.

How can different autonomic neurons have such contrasting effects? There are two fundamental reasons: (1) Sympathetic and parasympathetic neurons secrete different neurotransmitters, and (2) target cells respond in different ways even to the same neurotransmitter depending on what type of receptors they have for it. All autonomic neurons secrete either acetylcholine or norepinephrine, and each of these neurotransmitters has two major classes of receptors (fig. 15.8).

- **Acetylcholine (ACh).** ACh is secreted by the preganglionic neurons in both divisions and the postganglionic neurons of the parasympathetic division (table 15.4). A few sympathetic postganglionics also secrete ACh—those that innervate sweat glands and some blood vessels. Any neuron that secretes ACh is called a **cholinergic neuron** (CO-lin-UR-jic), and any receptor that binds it is called a **cholinergic receptor**. There are two categories of cholinergic receptors:
 - **Muscarinic receptors** (MUSS-cuh-RIN-ic). These are named for muscarine, a mushroom toxin used in their discovery. All cardiac muscle, smooth muscle, and gland cells with cholinergic innervation have muscarinic receptors. There are different subclasses of muscarinic receptors with different effects; thus ACh excites intestinal

FIGURE 15.8 Neurotransmitters and Receptors of the Autonomic Nervous System. (a) All parasympathetic neurons are cholinergic. (b) Most sympathetic postganglionic neurons are adrenergic; they secrete norepinephrine (NE), and the target cell bears adrenergic receptors. (c) A few sympathetic postganglionic neurons are cholinergic; they secrete acetylcholine (ACh), and the target cell has cholinergic receptors of the muscarinic class.

smooth muscle by binding to one type of muscarinic receptor, and inhibits cardiac muscle by binding to a different type. Muscarinic receptors work through a variety of second-messenger systems.

- **Nicotinic receptors** (NIC-oh-TIN-ic). These are named for another botanical toxin helpful to their discovery—nicotine. They occur at all synapses in the autonomic ganglia, where the preganglionic fibers stimulate the postganglionic cells; on cells of the adrenal medulla; and at the neuromuscular junctions of skeletal muscle fibers. The binding of ACh to a nicotinic receptor is always excitatory. Nicotinic receptors work by opening ligand-gated ion channels and producing an excitatory postsynaptic potential in the target cell.

TABLE 15.4

Locations of Cholinergic and Adrenergic Fibers in the ANS

Division	Preganglionic Fibers	Postganglionic Fibers
Sympathetic	Always cholinergic	Mostly adrenergic; a few cholinergic
Parasympathetic	Always cholinergic	Always cholinergic

- **Norepinephrine (NE).** This neurotransmitter is secreted by nearly all sympathetic postganglionic fibers (table 15.4). Neurons that secrete NE are called **adrenergic neurons**, and the receptors for it are called **adrenergic receptors**. (NE is also called noradrenaline, the origin of the term *adrenergic*.) There are two principal categories of adrenergic receptors, alpha (α) and beta (β):
 - **α -adrenergic receptors.** These usually have excitatory effects. For example, the binding of NE to α -adrenergic receptors promotes labor contractions, stimulates pilo-erection, and constricts dermal blood vessels, yet it inhibits intestinal motility. These contrasting effects result from the different actions of two subclasses of α -adrenergic receptors— α_1 and α_2 . Receptors of the α_1 type act through calcium ions as a second messenger, whereas α_2 receptors inhibit the synthesis of cyclic AMP (cAMP).
 - **β -adrenergic receptors.** These are usually inhibitory. For example, NE relaxes and dilates the bronchioles (thus enhancing respiratory airflow) when it binds to β -adrenergic receptors of the smooth muscle. Yet when it binds to the β -adrenergic receptors of cardiac muscle, it has an excitatory effect. Such contrasting effects—increased pulmonary airflow and a stronger, faster heartbeat—are obviously appropriate to a state of exercise. Here again there are two receptor subclasses, β_1 and β_2 , which mediate different effects. Both types, however, act through cAMP as a second messenger.

Table 15.5 summarizes the effects of sympathetic and parasympathetic stimulation on different target organs and shows how some of these effects hinge on the receptor type. Knowledge of these receptor types is also vital to the field of neuropharmacology (see Deeper Insight 15.2). Many naturally occurring drugs bind selectively to one or another class or subclass of receptor. Atropine binds only to muscarinic receptors and curare only to nicotinic receptors, for example. Many synthetic drugs are designed to be similarly selective.

TABLE 15.5 Effects of the Sympathetic and Parasympathetic Nervous Systems

Target	Sympathetic Effect and Receptor Type	Parasympathetic Effect (All Muscarinic)
Adipose Tissue	Decreased fat breakdown (α)	No effect
	Increased fat breakdown (α , β)	
Eye		
Iris	Pupillary dilation (α)	Pupillary constriction
Ciliary muscle and lens	Relaxation for far vision (β)	Contraction for near vision
Lacrimal (tear) gland	None	Secretion
Integumentary System		
Merocrine sweat glands (cooling)	Secretion (muscarinic)	No effect
Apocrine sweat glands (scent)	Secretion (α)	No effect
Arrector pili muscles	Hair erection (α)	No effect
Endocrine System		
Adrenal Medulla	Hormone secretion (nicotinic)	No effect
Circulatory System		
Heart rate and force	Increased (β)	Decreased
Deep coronary arteries	Vasodilation (β)	Slight vasodilation
	Vasoconstriction (α)	
Blood vessels of most viscera	Vasoconstriction (α)	Vasodilation
Blood vessels of skin	Vasoconstriction (α)	Vasodilation, blushing
Platelets (blood clotting)	Increased clotting (α)	No effect
Respiratory System		
Bronchi and bronchioles	Bronchodilation (β)	Bronchoconstriction
Mucous glands	Decreased secretion (α)	No effect
	Increased secretion (β)	
Urinary System		
Kidneys	Reduced urine output (α)	No effect
Bladder wall	No effect	Contraction
Internal urethral sphincter (absent from females)	Contraction, urine retention (α)	Relaxation, urine release
Digestive System		
Salivary glands	Thick mucous secretion (α)	Thin serous secretion
Gastrointestinal motility	Decreased (α , β)	Increased
Gastrointestinal secretion	Decreased (α)	Increased
Liver	Glycogen breakdown (α , β)	Glycogen synthesis
Pancreatic enzyme secretion	Decreased (α)	Increased
Pancreatic insulin secretion	Decreased (α)	No effect
	Increased (β)	
Reproductive System		
Penile or clitoral erection	No effect	Stimulation
Glandular secretion	No effect	Stimulation
Orgasm, smooth muscle roles	Stimulation (α)	No effect
Uterus	Relaxation (β)	No effect
	Labor contractions (α)	

The autonomic effects on glandular secretion are often the indirect results of action on blood vessels. Many glandular secretions begin as a filtrate of the blood, which is then modified by the gland cells. Increasing the blood flow through a gland (such as a salivary or sweat gland) tends to increase secretion, and reducing the blood flow reduces secretion.

Sympathetic effects tend to last longer than parasympathetic effects. After a parasympathetic fiber secretes ACh onto its target cells, it is quickly broken down by acetylcholinesterase (AChE) and its effect lasts only a few seconds. The NE released by a sympathetic fiber, however, has various fates: (1) Some is reabsorbed by the axon terminals, where it is either reused or broken down by an enzyme called *monoamine oxidase (MAO)*. (2) Some diffuses into the adjacent tissues, where it is degraded by another enzyme, *catechol-O-methyltransferase (COMT)*. (3) Much of it passes into the bloodstream, where MAO and COMT are absent. This NE and epinephrine from the adrenal gland circulate throughout the body and may exert their effects for several minutes before they are finally degraded by the liver. This provides sympathetic stimulation for target cells that aren't directly innervated.

ACh and NE are not the only neurotransmitters employed by the ANS. Although all autonomic fibers secrete one of these, many of them also secrete neuropeptides that modulate ACh or NE function. Sympathetic fibers may also secrete enkephalin, substance P, neuropeptide Y, somatostatin, neurotensin, or gonadotropin-releasing hormone. Some parasympathetic fibers relax blood vessels by stimulating the endothelial cells to release nitric oxide (NO), a gas. NO inhibits smooth muscle tone in the vessel wall, thus allowing the vessel to dilate. This increases the blood flow through the vessel. Among other functions, this mechanism is crucial to penile erection.

▶▶▶ APPLY WHAT YOU KNOW

Table 15.5 notes that the sympathetic nervous system has an α -adrenergic effect on blood platelets and promotes clotting. How can it stimulate platelets, considering that platelets are drifting cell fragments in the bloodstream with no nerve fibers leading to them?

15.3b Dual Innervation

Most of the viscera receive nerve fibers from both the sympathetic and parasympathetic divisions and thus are said to have **dual innervation**. In such cases, the two divisions may have either *antagonistic* or *cooperative* effects on the same organ.

Antagonistic effects oppose each other. For example, the sympathetic division speeds up the heart and the parasympathetic division slows it down; the sympathetic division inhibits digestion and the parasympathetic division stimulates it; the sympathetic division dilates the pupil and the parasympathetic division constricts it. In some cases, these effects are exerted through dual innervation of the same effector cells, as in the heart, where nerve

fibers of both divisions stimulate some of the same cells. In other cases, antagonistic effects arise because each division innervates different effector cells with opposite effects on organ function. In the iris of the eye, for example, sympathetic fibers innervate pupillary dilator cells and parasympathetic fibers innervate constrictor cells (**fig. 15.9**).

Cooperative effects are seen when the two divisions act on different effectors to produce a unified overall effect. Salivation is a good example. The parasympathetic division stimulates serous cells of the salivary glands to secrete a watery, enzyme-rich secretion, while the sympathetic division stimulates mucous cells of the same glands to secrete mucus. The enzymes and mucus are both necessary components of the saliva.

FIGURE 15.9 Dual Innervation of the Iris. Shows antagonistic effects of the sympathetic (yellow) and parasympathetic (blue) divisions on the iris.

? If a person is in a state of fear, would you expect the pupils to be dilated or constricted? Why?

Even when different autonomic divisions innervate a single organ, they don't always innervate it equally or exert equal influence. For example, the parasympathetic division and enteric plexus exert much more influence on the digestive tract than the sympathetic division does. In the ventricles of the heart, by contrast, there is much less parasympathetic than sympathetic innervation.

15.3c Control Without Dual Innervation

Dual innervation isn't always necessary for the ANS to produce opposite effects on an organ. The adrenal medulla, arrector muscles, sweat glands, and many blood vessels receive only sympathetic fibers. The most significant examples of control without dual innervation are regulation of blood pressure and routes of blood flow. The sympathetic fibers to a blood vessel have a baseline sympathetic tone, which keeps the vessels in a state of partial constriction called **vasomotor tone** (fig. 15.10). An increase in firing rate constricts a vessel by increasing smooth muscle contraction. A drop in firing frequency dilates a vessel by allowing the smooth muscle to relax. The blood pressure in the vessel, pushing outward on its wall and meeting less resistance, then dilates the vessel. Thus, the sympathetic division alone exerts opposite effects on the vessels.

Sympathetic control of vasomotor tone can shift blood flow from one organ to another according to the changing needs of the body. In times of emergency, stress, or exercise, the skeletal muscles and heart receive a high priority and the sympathetic division dilates the arteries that supply them. Processes such as digestion, nutrient absorption, and urine formation can wait; thus, the sympathetic division constricts arteries to the gastrointestinal tract and kidneys. It also reduces blood flow through the skin, which may help to minimize bleeding in the event that the stress-producing situation leads to injury. Furthermore, since there isn't enough blood in the body to supply all the organ systems equally, it's necessary to temporarily divert blood away from some organs in order to supply an adequate amount to the muscular system.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

7. What neurotransmitters are secreted by adrenergic and cholinergic fibers?
8. Why do sympathetic effects last longer than parasympathetic effects?
9. How can the sympathetic division cause smooth muscle to relax in some organs but contract in others?
10. What are the two ways in which the sympathetic and parasympathetic systems can affect each other when they both innervate the same target organ? Give examples.
11. How can the sympathetic nervous system have contrasting effects in a target organ without dual innervation?

(a) Vasoconstriction

(b) Vasodilation

FIGURE 15.10 Sympathetic and Vasomotor Tone.

(a) Vasoconstriction in response to a high rate of sympathetic nerve firing. (b) Vasodilation in response to a low rate of sympathetic nerve firing. Smooth muscle relaxation allows blood pressure within the vessel to push the vessel wall outward. Black lines crossing each nerve fiber represent action potentials, with a high firing frequency in part (a) and a lower frequency in part (b).

15.4 Central Control of Autonomic Function

Expected Learning Outcomes

When you have completed this section, you should be able to

- identify what parts of the brain influence the autonomic nervous system;
- give examples of emotional influences on autonomic function; and
- give examples of spinal cord control over autonomic functions.

In spite of its name, the autonomic nervous system is not an independent nervous system. In this section we briefly consider how it is influenced by various levels of the central nervous system.

- **Cerebral cortex.** Even if we usually can't consciously control the ANS, it's clear that the mind influences it. Anger raises the blood pressure, fear makes the heart race, thoughts of good food make the stomach rumble, sexual thoughts or stimulation increase blood flow to the genitals, and anxiety inhibits sexual function. The limbic system, an ancient part of the cerebrum, is involved in many emotional responses and has extensive connections with the hypothalamus, a site of several nuclei of autonomic control. Thus, the limbic system provides a pathway connecting sensory and emotional experiences with the autonomic nervous system.
- **Hypothalamus.** The major control center of the visceral motor system is the hypothalamus. This small but vital region in the floor of the brain contains many nuclei for primitive functions, including hunger, thirst, thermoregulation, emotions, and sexuality. Artificial stimulation of different regions of the hypothalamus can activate the fight-or-flight response typical of the sympathetic nervous system or have the calming effects typical of the parasympathetic. Output from the hypothalamus travels largely to nuclei in the brainstem, and from there to the cranial nerves and the sympathetic neurons in the spinal cord.
- **Midbrain, pons, and medulla oblongata.** These regions of the brainstem house numerous autonomic nuclei described in section 14.3: centers for cardiac and vasomotor control,

salivation, swallowing, sweating, gastrointestinal secretion, bladder control, pupillary constriction and dilation, and other primitive functions. Many of these nuclei belong to the reticular formation, which extends from the medulla to the hypothalamus. Autonomic output from these nuclei travels by way of the spinal cord and the oculomotor, facial, glossopharyngeal, and vagus nerves.

- **Spinal cord.** Finally, the spinal cord integrates such autonomic reflexes as micturition (urination), defecation, erection, and ejaculation, detailed in later chapters. Fortunately, the brain is able to inhibit defecation and urination consciously, but when injuries sever the spinal cord from the brain, the autonomic spinal reflexes alone control the elimination of urine and feces.

Table 15.6 describes some dysfunctions of the autonomic nervous system.

BEFORE YOU GO ON

- Answer the following questions to test your understanding of the preceding section:
12. What system in the brain connects our conscious thoughts and feelings with the autonomic control centers of the hypothalamus?
 13. List some autonomic responses that are controlled by nuclei in the hypothalamus.
 14. What are the roles of the midbrain, pons, and medulla in autonomic control?
 15. Name some visceral reflexes controlled by the spinal cord.

TABLE 15.6 Some Disorders of the Autonomic Nervous System

Horner ¹⁴ syndrome	Chronic unilateral pupillary constriction, sagging of the eyelid, withdrawal of the eye into the orbit, flushing of the skin, and lack of facial perspiration; results from lesions in the cervical ganglia, upper thoracic spinal cord, or brainstem that interrupt sympathetic innervation of the head.
Orthostatic (postural) hypotension ¹⁵	Sudden drop in blood pressure upon rising from a recumbent or sitting position, causing dizziness and sometimes fainting or falling. Results from an insufficiently quick autonomic cardiovascular response to postural change. May be caused by a variety of factors including medications and underlying diseases. Becomes more common with advancing age.
Raynaud ¹⁶ disease	Intermittent attacks of paleness, cyanosis, and pain in the fingers and toes, caused when cold or emotional stress triggers excessive vasoconstriction in the digits; most common in young women. In extreme cases, causes gangrene and may require amputation. Sometimes treated by severing sympathetic nerves to the affected regions.

You can find other autonomic nervous system disorders described in the following places:
The *mass reflex reaction* in Deeper Insight 13.5; *autonomic effects of cranial nerve injuries* in section 14.6c; and *Hirschsprung disease* and *Chagas disease* in Deeper Insight 15.1.

¹⁴Johann F. Horner (1831–86), Swiss ophthalmologist

CLINICAL APPLICATION

Drugs and the Nervous System

Neuropharmacology is a branch of medicine that deals with the effects of drugs on the nervous system, especially drugs that mimic, enhance, or inhibit the action of neurotransmitters. A few examples will illustrate the clinical relevance of neurotransmitter and receptor functions.

A number of drugs work by stimulating adrenergic and cholinergic neurons or receptors. *Sympathomimetics*¹⁷ are drugs that enhance sympathetic action. They stimulate adrenergic receptors or promote norepinephrine release. For example, phenylephrine, found in such cold medicines as Dimetapp and Sudafed PE, aids breathing by stimulating α -adrenergic receptors, dilating the bronchioles, and constricting nasal blood vessels, thus reducing swelling in the nasal mucosa. *Sympatholytics*¹⁸ are drugs that suppress sympathetic action by inhibiting norepinephrine release or by binding to adrenergic receptors without stimulating them. Propranolol, for example, is a *beta-blocker*. It reduces high blood pressure partly by blocking β -adrenergic receptors. This interferes with the effects of epinephrine and norepinephrine on the heart and blood vessels. (It also reduces the production of *angiotensin II*, a hormone that stimulates vasoconstriction and raises blood pressure.)

Parasympathomimetics enhance parasympathetic effects. Pilocarpine, for example, relieves glaucoma (excessive pressure in the eyeball) by dilating a vessel that drains fluid from the eye. *Parasympatholytics* inhibit ACh release or block its receptors. Atropine, for example, blocks muscarinic receptors. It is sometimes used to dilate the pupils for eye examinations and to dry the mucous membranes of the respiratory tract before inhalation anesthesia. It is an extract of the deadly nightshade plant, *Atropa belladonna*.¹⁹ Women of the Middle Ages used nightshade to dilate their pupils, which was regarded as a beauty enhancement.

The drugs mentioned so far act on the peripheral nervous system and its effectors. Many others act on the central nervous system. Strychnine, for example, blocks the inhibitory action of glycine on spinal motor neurons. The neurons then overstimulate the muscles, causing spastic paralysis and sometimes death by suffocation.

Sigmund Freud predicted that psychiatry would eventually draw upon biology and chemistry to deal with emotional problems once treated only by counseling and psychoanalysis. A branch of neuropharmacology called *psychopharmacology* has fulfilled his prediction.

The management of clinical depression is one example of how contemporary psychopharmacology has supplemented counseling approaches. Some forms of depression result from deficiencies of the monoamine neurotransmitters. Thus, they yield to drugs that prolong the effects of the monoamines already present at the synapses. Prozac (fluoxetine), for example, blocks serotonin reuptake and prolongs its mood-elevating effect; thus Prozac is called a *selective serotonin reuptake inhibitor (SSRI)*. It is also used to treat fear of rejection, excess sensitivity to criticism, lack of self-esteem, and inability to experience pleasure, all of which were long handled only through counseling, group therapy, or psychoanalysis. After monoamines are taken up from the synapse, they are degraded by monoamine oxidase (MAO). Drugs called *MAO inhibitors* slow down the breakdown of monoamine neurotransmitters and provide another pharmacological approach to depression.

Our growing understanding of neurochemistry also gives us more insight into the action of addictive drugs of abuse such as amphetamines and cocaine. Amphetamines (“speed”) chemically resemble

norepinephrine and dopamine, two neurotransmitters associated with elevated mood. Dopamine is especially important in sensations of pleasure. Cocaine blocks dopamine reuptake and thus produces a brief rush of good feelings. But when dopamine isn’t reabsorbed by the neurons, it diffuses out of the synaptic cleft and is degraded elsewhere. Cocaine thus depletes the neurons of dopamine faster than they can synthesize it, so finally there is no longer an adequate supply to maintain normal mood. The postsynaptic neurons make new dopamine receptors as if “searching” for the neurotransmitter—all of which leads ultimately to anxiety, depression, and the inability to experience pleasure without the drug.

Caffeine exerts its stimulatory effect by competing with adenosine. Adenosine, which you know as a component of DNA, RNA, and ATP, also functions as a neuromodulator in the brain, inhibiting ACh release by cholinergic neurons. One theory of sleepiness is that it results when prolonged metabolic activity breaks down so much ATP that the accumulated adenosine has a noticeably inhibitory effect. Caffeine has enough structural similarity to adenosine (**fig. 15.11**) to bind to its receptors, but it doesn’t produce the inhibitory effect. Thus, it prevents adenosine from exerting its effect, more ACh is secreted, and a person feels more alert.

FIGURE 15.11 Adenosine and Caffeine. Adenosine, a breakdown product of ATP and other chemicals, inhibits ACh release and produces a sense of sleepiness. Caffeine is similar enough to block the action of adenosine by binding to its receptors. This results in increased ACh release and heightened arousal.

¹⁷mimet = imitate, mimic

¹⁸lyt = break down, destroy

¹⁹bella = beautiful, fine; donna = woman

STUDY GUIDE

► Assess Your Learning Outcomes

To test your knowledge, discuss the following topics with a study partner or in writing, ideally from memory.

15.1 General Properties of the Autonomic Nervous System

1. The fundamental function and effectors of the autonomic nervous system (ANS)
2. Why this system is called *autonomic*; how it differs from the somatic motor system
3. The fundamental, contrasting functions of the sympathetic and parasympathetic divisions of the ANS
4. Why it cannot be said that at any given moment, either the sympathetic or the parasympathetic division is active; the meaning of *autonomic tone*
5. Basic anatomical components of the ANS
6. How autonomic efferent pathways differ from somatic efferent pathways; the meanings of *preganglionic* and *postganglionic fibers*

15.2 Anatomy of the Autonomic Nervous System

1. Origin of the sympathetic preganglionic fibers and the routes they take to the sympathetic chain ganglia
2. Anatomy of the sympathetic chain; the number of ganglia at its various levels; and the body regions supplied by nerve fibers issuing from each group of ganglia
3. The gray and white communicating rami that connect the sympathetic ganglia to the spinal nerves; the reason they are named

- gray and white; and the path that sympathetic nerve fibers take through these rami
4. Differences between the spinal nerve route, sympathetic nerve route, and splanchnic nerve route by which fibers leave the sympathetic chain
 5. Various places in which a sympathetic preganglionic fiber may synapse with a postganglionic neuron
 6. Locations of the celiac, superior mesenteric ganglia, and inferior mesenteric ganglia; the collective name for them; and the varied meanings of the expression *solar plexus*
 7. The degree and significance of neural divergence in the sympathetic nervous system, and the effect of this on target organ stimulation
 8. Why the adrenal medulla can be considered part of the sympathetic nervous system; what products it secretes when stimulated
 9. Names and numbers of the cranial and spinal nerves that carry preganglionic fibers of the parasympathetic nervous system; which nerve carries the largest percentage of parasympathetic fibers
 10. The path of the vagus nerve, and the names and locations of the plexuses and trunks to which it gives rise
 11. Where, in general, terminal ganglia of the parasympathetic division are found, and therefore where the postganglionic fibers begin
 12. The location and functions of the enteric plexus

15.3 Autonomic Effects on Target Organs

1. Why the autonomic effect on a target cell depends on both the neurotransmitter released and the type of receptor on the target cell
2. The difference between cholinergic and adrenergic fibers and where each can be found in the ANS
3. What nicotinic and muscarinic receptors have in common, how they differ, and where they occur in the ANS
4. What α - and β -adrenergic receptors have in common, how they differ, and where they occur in the ANS
5. Neurotransmitter stability and how it relates to the duration of sympathetic versus parasympathetic effects
6. The variety of neurotransmitters and neuromodulators employed by them
7. Autonomic control of certain organs by dual innervation, and examples of antagonistic and cooperative effects on an organ
8. How the ANS can regulate organs that lack dual innervation

15.4 Central Control of Autonomic Function

1. Examples of the influence of the cerebral cortex, hypothalamus, midbrain, pons, medulla oblongata, and spinal cord on the autonomic nervous system, and their involvement in autonomic effects

► Testing Your Recall

Answers in Appendix A

1. The autonomic nervous system innervates all of these *except*
 - a. cardiac muscle.
 - b. skeletal muscle.
 - c. smooth muscle.
 - d. salivary glands.
 - e. blood vessels.
2. Muscarinic receptors bind
 - a. epinephrine.
 - b. norepinephrine.
 - c. acetylcholine.
 - d. cholinesterase.
 - e. neuropeptides.
3. All of the following cranial nerves *except* the _____ carry parasympathetic fibers.
 - a. vagus
 - b. facial
 - c. oculomotor
 - d. glossopharyngeal
 - e. hypoglossal

STUDY GUIDE

4. Which of the following cranial nerves carries sympathetic fibers?
 - a. oculomotor
 - b. facial
 - c. trigeminal
 - d. vagus
 - e. none of them
5. Which of these ganglia is *not* involved in the sympathetic division?
 - a. intramural
 - b. superior cervical
 - c. paravertebral
 - d. inferior mesenteric
 - e. celiac
6. Epinephrine is secreted by
 - a. sympathetic preganglionic fibers.
 - b. sympathetic postganglionic fibers.
 - c. parasympathetic preganglionic fibers.
 - d. parasympathetic postganglionic fibers.
 - e. the adrenal medulla.
7. The most significant autonomic control center within the CNS is
 - a. the cerebral cortex.
 - b. the limbic system.
 - c. the midbrain.
 - d. the hypothalamus.
 - e. the sympathetic chain ganglia.
8. The gray communicating ramus contains
 - a. visceral sensory fibers.
 - b. parasympathetic motor fibers.
 - c. sympathetic preganglionic fibers.
 - d. sympathetic postganglionic fibers.
 - e. somatic motor fibers.
9. Throughout the autonomic nervous system, the neurotransmitter released by the preganglionic fiber binds to _____ receptors on the postganglionic neuron.
 - a. nicotinic
 - b. muscarinic
 - c. adrenergic
 - d. alpha
 - e. beta
10. Which of these does *not* result from sympathetic stimulation?
 - a. dilation of the pupil
 - b. acceleration of the heart
 - c. digestive secretion
 - d. enhanced blood clotting
 - e. piloerection
11. Certain nerve fibers are called _____ fibers because they secrete norepinephrine.
12. _____ is a state in which a target organ receives both sympathetic and parasympathetic fibers.
13. _____ is a state of continual background activity of the sympathetic and parasympathetic divisions.
14. Most parasympathetic preganglionic fibers are found in the _____ nerve.
15. The digestive tract has a semi-independent nervous system called the _____ nervous system.
16. MAO and COMT are enzymes that break down _____ at certain ANS synapses.
17. The adrenal medulla consists of modified postganglionic neurons of the _____ nervous system.
18. The sympathetic nervous system has short _____ and long _____ nerve fibers.
19. Adrenergic receptors classified as α_1 , β_1 , and β_2 act by changing the level of _____ in the target cell.
20. Sympathetic fibers to blood vessels maintain a state of partial vasoconstriction called _____.

► Building Your Medical Vocabulary

Answers in Appendix A

State a meaning of each word element, and give a medical term from this chapter that uses it or a slight variation of it.

- | | | |
|----------|-----------|---------------|
| 1. baro- | 3. muro- | 7. reno- |
| 2. lyto- | 4. nomo- | 8. splanchno- |
| | 5. oto- | 9. sym- |
| | 6. patho- | 10. viscero- |

► What's Wrong with These Statements?

Answers in Appendix A

Briefly explain why each of the following statements is false, or reword it to make it true.

- | | | |
|---|--|--|
| 1. The parasympathetic nervous system shuts down when the sympathetic nervous system is active, and vice versa. | 4. The sympathetic nervous system stimulates digestion. | 8. Sympathetic effects are more localized and organ-specific than parasympathetic effects. |
| 2. The parasympathetic nervous system controls dilation and constriction of the blood vessels of the skin. | 5. All sympathetic postganglionic fibers are adrenergic. | 9. The oculomotor, facial, hypoglossal, and vagus nerves carry the parasympathetic fibers that arise from the brain. |
| 3. Voluntary control of the ANS is not possible. | 6. Urination and defecation cannot occur without signals from the brain to the bladder and rectum. | 10. The two divisions of the ANS have cooperative effects on the iris. |
| | 7. Some parasympathetic nerve fibers are adrenergic. | |

STUDY GUIDE

► Testing Your Comprehension

1. You are dicing raw onions while preparing dinner, and the vapor makes your eyes water. Describe the afferent and efferent pathways involved in this response.
2. Suppose you are walking alone at night when you hear a dog growling close behind you. Describe the ways your sympathetic nervous system would prepare you to deal with this situation.
3. Suppose that the cardiac nerves were destroyed. How would this affect the heart and the body's ability to react to a stressful situation?
4. What would be the advantage to a wolf in having its sympathetic nervous system stimulate the arrector muscles? What happens in a human when the sympathetic system stimulates these muscles?
5. Pediatric literature has reported many cases of poisoning in children with Lomotil, an antidiarrheal medicine. Lomotil works primarily by means of the morphinelike effects of its chief ingredient, diphenoxylate, but it also contains atropine. Considering the mode of action described for atropine in Deeper Insight 15.2, why might it contribute to the antidiarrheal effect of Lomotil? In atropine poisoning, would you expect the pupils to be dilated or constricted? The skin to be moist or dry? The heart rate to be elevated or depressed? The bladder to retain urine or void uncontrollably? Explain each answer. Atropine poisoning is treated with physostigmine, a cholinesterase inhibitor. Explain the rationale of this treatment.

SENSE ORGANS

Iris of the eye. The intricacy and uniqueness of the iris is being used increasingly for identity verification.

BRUSHING UP

- Understanding how some senses work—including taste and smell—hinges on a knowledge of G proteins, cAMP, and second-messenger systems, explained in figure 3.8 and the associated text.
- This chapter's description of the hearing process assumes prior knowledge of mechanically gated membrane channels (see section 3.2a) and ion flow down an electrochemical gradient (see section 11.3c).
- Several concepts in section 12.6 are important for understanding sensory processes: postsynaptic potentials (EPSPs and IPSPs), temporal and spatial summation, neural coding, and converging neural circuits.
- You will need to remember the concepts of spinal cord tracts and decussation (see section 13.1e) to understand sensory pathways from lower-body receptors to the brain.
- Familiarity with certain cranial nerves is necessary for understanding other sensory pathways to the brain—especially the olfactory, optic, trigeminal, facial, vestibulocochlear, glossopharyngeal, and vagus nerves, all described in table 14.1.
- You must know the gross anatomy of the brain, especially lobes and gyri of the cerebral cortex, to understand where sensory signals are received and processed (see section 14.4b).
- To understand the anatomy of the ear, it will be helpful to recall the anatomy of the temporal bone (see “The Temporal Bones” in section 8.2a).

Anyone who enjoys music, art, fine food, or a good conversation appreciates the human senses. Yet their importance extends far beyond deriving pleasure from the environment. In the 1950s, behavioral scientists at Princeton University studied the methods used by Soviet Communists to extract confessions from political prisoners, including solitary confinement and sensory deprivation. Student volunteers were immobilized in dark soundproof rooms or suspended in dark chambers of water. In a short time, they experienced visual, auditory, and tactile hallucinations, incoherent thought patterns, extreme suggestibility, deterioration of intellectual performance, and sometimes morbid fear or panic. Similar effects are seen in some burn patients who are immobilized and extensively bandaged (including the eyes) and thus suffer prolonged lack of sensory input. Patients connected to life-support equipment and confined under oxygen tents sometimes become delirious. Sensory input is vital to the integrity of personality and intellectual function.

Furthermore, much of the information communicated by the sense organs never comes to our conscious attention—blood pressure, body temperature, and muscle tension, for example. By monitoring such conditions, however, the sense organs initiate somatic and visceral reflexes that are indispensable to homeostasis and to our very survival in a ceaselessly changing and challenging environment.

16.1 Properties and Types of Sensory Receptors

Expected Learning Outcomes

When you have completed this section, you should be able to

- define *receptor* and *sense organ*;
- list the four kinds of information obtained from sensory receptors, and describe how the nervous system encodes each type; and
- outline three ways of classifying receptors.

A sensory **receptor** is any structure specialized to detect a stimulus. Some receptors are simple, bare nerve endings, such as the receptors for heat and pain, whereas others are true sense organs. A **sense organ** is a structure that combines nervous tissue with other tissues that enhance its response to a certain type of stimulus. The accessory tissues may include epithelial, muscular, or connective tissue. Sense organs can be as complex as the eye and ear or as microscopic and simple as a dendrite wrapped in a little bit of connective tissue.

16.1a General Properties of Receptors

The fundamental purpose of any sensory receptor is **transduction**, the conversion of one form of energy to another—light, sound, heat, touch, vibration, or other forms of stimulus energy into nerve signals. (Any device that converts one energy form to another is a *transducer*—whether a sense organ, gasoline engine, or lightbulb.)

There are two stages in the sensory process—*sensation* and *perception*. **Sensation** is the stage in which a sensory receptor detects its environment and exhibits a small local electrical change called a **receptor potential**. In many cases, such as the senses of touch and smell, the sensory cell is a neuron. If the receptor potential is strong enough, the neuron fires off a volley of action potentials, generating a nerve signal to the CNS. In other cases, such as taste and hearing, the sensory cell isn't a neuron but an epithelial cell. Nevertheless, it has synaptic vesicles at its base; it releases a neurotransmitter in response to a stimulus; and it stimulates an adjacent neuron. That neuron then generates signals to the CNS.

Not all sensory signals go to the brain, but when they do, we may experience **perception**—conscious experience and interpretation of the stimulus. Perception is built on sensations, whereas not all sensations lead to perception. Indeed, most sensory signals delivered to the CNS produce no conscious perception at all. Most are filtered out in the brainstem before reaching the cerebral cortex, a valuable function that keeps us from being driven mad by innumerable unimportant stimuli detected by the sense organs. Other nerve signals concern functions that don't require conscious awareness, such as monitoring blood pH and body temperature.

Sensory receptors transmit four kinds of information—*modality*, *location*, *intensity*, and *duration*:

1. **Modality** refers to the type of stimulus or the perception it produces. Vision, hearing, and taste are examples of sensory modalities, as are subcategories of these such as red or blue

light, bass or treble sounds. The action potentials for vision are identical to the action potentials for taste or any other modality—so how can the brain tell a visual signal from a taste signal? Modality is determined by where the sensory signals end in the brain. Hypothetically, if we could rewire the brain so signals from the ear were routed to the visual cortex of the occipital lobe, we would perceive acoustic signals as light rather than sound.

2. **Location** is also encoded by which neurons issue signals to the brain. Any sensory neuron detects stimuli within an area called its **receptive field**. In the sense of touch, for example, a single sensory neuron may cover an area of skin as large as 7 cm in diameter. No matter where the skin is touched within that field, it stimulates the same neuron. The brain may be unable to determine whether the skin was touched at “point A” or at some other point 1 or 2 cm away. If the skin is simultaneously touched at two places in the same field, it can feel like a single touch (**fig. 16.1a**). In some areas of the body such as the back, this is sufficient; it isn’t necessary to make finer distinctions. On the other hand, we must be able to localize touch much more precisely with the fingertips. Here, each sensory neuron may cover a receptive field 1 mm or less in diameter—there is a much higher density of tactile nerve endings. Two points of contact just 2 mm apart will be felt as separate touches (**fig. 16.1b**). That is, the fingertips have finer *two-point touch discrimination* than the skin of the back. You

can imagine the importance of this in reading braille, appreciating the texture of a fine fabric, or manipulating an object as small as a sesame seed. The receptive field concept pertains not only to touch, but also to other senses such as vision.

3. **Intensity** refers to whether a sound is loud or soft, a light is bright or dim, a pain is mild or excruciating, and so forth. It is encoded in three ways: (a) As stimulus intensity rises, the firing frequencies of sensory nerve fibers rise (see **fig. 12.30**); (b) intense stimuli recruit greater numbers of neurons to fire; and (c) weak stimuli activate only the most sensitive neurons, whereas strong stimuli can activate a less sensitive group of neurons with higher thresholds. Thus, the brain can distinguish intensities based on which neurons are firing, how many are doing so, and how fast they are firing.
4. **Duration**, or how long a stimulus lasts, is encoded by changes in firing frequency with the passage of time. All receptors exhibit the property of **sensory adaptation**—if the stimulus is prolonged, the firing of the neuron gets slower over time, and with it, we become less aware of the stimulus. Adapting to hot bathwater is an example of this. Receptors are classified according to how quickly they adapt. **Phasic receptors** generate a burst of action potentials when first stimulated, then quickly adapt and sharply reduce or stop signaling even if the stimulus continues. Some of them fire again when the stimulus ceases. Phasic receptors are found in the senses of smell, hair movement, and cutaneous pressure and vibration.

FIGURE 16.1 Receptive Fields. (a) A neuron with a large receptive field, as found in the skin of the back. If the skin is touched in two close-together places within this receptive field, the brain senses it as only one point of contact. (b) Neurons with small receptive fields, as found in the fingertips. Two close-together points of contact here are likely to stimulate two different neurons and be felt as separate touches.

? If the receptive field in part (a) is 7 cm in diameter, is it ever possible for two touches 1 cm apart to be felt separately?

Their phasic nature explains why we may notice a suspicious odor such as a gas leak for several seconds, then the perception fades in intensity even if the stimulus is still there. If we don't find the gas leak quickly, it becomes difficult to find it at all. **Tonic receptors** adapt more slowly and generate signals more steadily. Proprioceptors and pain receptors are among the most persistently responding tonic receptors because the brain must always be aware of body position, muscle tension, joint motion, or a pain.

▶▶▶ APPLY WHAT YOU KNOW

Although you may find it difficult to immerse yourself in a tub of hot water or a cold lake, you soon adapt and become more comfortable. In light of this, do you think cold and warm receptors are phasic or tonic? Explain.

16.1b Classification of Receptors

Receptors can be classified by various overlapping systems:

- By stimulus modality:
 - Thermoreceptors** respond to heat and cold. Many nerve endings in the skin are thermoreceptors.
 - Photoreceptors**, the eyes, respond to light.
 - Nociceptors**,¹ pain receptors, respond to tissue injury or situations that threaten to damage a tissue. Nociceptors are abundant in the skin and mucous membranes.
 - Chemoreceptors** respond to chemicals, including odors, tastes, and body fluid composition.
 - Mechanoreceptors** respond to physical deformation of a cell or tissue caused by vibration, touch, pressure, stretch, or tension. They include the organs of hearing and balance and many receptors of the skin, viscera, and joints.
- By the origin of the stimulus:
 - Exteroceptors** sense stimuli external to the body. They include the receptors for vision, hearing, taste, smell, and cutaneous senses such as touch, heat, cold, and pain.
 - Interoceptors** detect stimuli in the internal organs such as the stomach, intestines, and bladder, and produce feelings of stretch, pressure, visceral pain, and nausea.
 - Proprioceptors** sense the position and movements of the body or its parts. They occur in muscles, tendons, and joint capsules.
- By the distribution of receptors in the body. There are two broad classes of senses:
 - General (somatosensory, somesthetic) senses** employ widely distributed receptors in the skin, muscles, tendons, joints, and viscera. These include touch, pressure, stretch, heat, cold, and pain, as well as many stimuli that we don't perceive consciously, such as blood pressure and compo-

sition. Their receptors are relatively simple—sometimes nothing more than a bare dendrite.

- Special senses** are limited to the head, are innervated by the cranial nerves, and employ relatively complex sense organs. The special senses are vision, hearing, equilibrium, taste, and smell.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

- Not every sensory *receptor* is a *sense organ*. Explain.
- What does it mean to say sense organs are transducers? What form of energy do all receptors have as their output?
- Not every sensory signal results in conscious perception of a stimulus. Explain.
- What is meant by the *modality* of a stimulus? Give some examples.
- Three schemes of receptor classification were presented in this section. In each scheme, how would you classify the receptors for a full bladder? How would you classify taste receptors?
- Nociceptors are tonic rather than phasic receptors. Speculate on why this is beneficial to homeostasis.

16.2 The General Senses

Expected Learning Outcomes

When you have completed this section, you should be able to

- list several types of somatosensory receptors;
- describe the projection pathways for the general senses; and
- describe the types and mechanisms of pain, and explain how the brain modulates one's sensitivity to pain.

Receptors for the general senses are relatively simple in structure and physiology. They consist of one or a few sensory nerve endings and, usually, a sparse amount of connective tissue. These receptors are shown in **figure 16.2** and described in **table 16.1**.

16.2a Unencapsulated Nerve Endings

Unencapsulated nerve endings are dendrites with no connective tissue wrapping. They include the following:

- Free nerve endings** include *warm receptors*, which respond to rising temperature; *cold receptors*, which respond to falling temperature; and *nociceptors* for pain. They are bare dendrites that have no special association with specific accessory cells or tissues. They're most abundant in the skin and mucous membranes. You can locate some of your cold receptors by gently

¹*noc*i = pain

FIGURE 16.2 Receptors of the General Senses. See table 16.1 for functions.

TABLE 16.1 Receptors of the General Senses		
Receptor Type	Locations	Modality
Unencapsulated Endings		
Free nerve endings	Widespread, especially in epithelia and connective tissues	Pain, heat, cold
Tactile discs	Stratum basale of epidermis	Light touch, pressure
Hair receptors	Around hair follicle	Light touch, movement of hairs
Encapsulated Nerve Endings		
Tactile corpuscles	Dermal papillae of fingertips, palms, eyelids, lips, tongue, nipples, and genitals	Light touch, texture
End bulbs	Mucous membranes	Similar to tactile corpuscles
Bulbous corpuscles	Dermis, subcutaneous tissue, and joint capsules	Heavy continuous touch or pressure; joint movements
Lamellar corpuscles	Dermis, joint capsules, periosteum, breasts, genitals, and some viscera	Deep pressure, stretch, tickle, vibration
Muscle spindles	Skeletal muscles near tendon	Muscle stretch (proprioception)
Tendon organs	Tendons	Tension on tendons (proprioception)

touching your skin with the point of a graphite pencil, which conducts heat away from the skin. In spots where these receptors are located, this is felt as cooling of the skin.

- **Tactile (Merkel²) discs** are tonic receptors for light touch, thought to sense textures, edges, and shapes. They are flattened nerve endings that terminate adjacent to specialized *tactile cells* in the basal layer of the epidermis. They respond to compression of the skin, which releases a chemical from the tactile cell that excites the associated nerve fiber.
- **Hair receptors (root hair plexuses)** are dendrites that coil around a hair follicle and respond to movements of the hair. They are stimulated when, for example, an ant walks across one's skin, bending one hair after another. However, they adapt quickly, so we aren't constantly irritated by the feel of clothing against the skin. Hair receptors are particularly important in the eyelashes, where the slightest touch evokes a protective blink reflex.

16.2b Encapsulated Nerve Endings

Encapsulated nerve endings are nerve fibers wrapped in glial cells or connective tissue. Most of them are mechanoreceptors for touch, pressure, and stretch. The connective tissue either enhances the sensitivity of the nerve fiber or makes it more selective with respect to which modality it responds to. The principal encapsulated nerve endings are as follows:

- **Tactile (Meissner³) corpuscles** are phasic receptors for light touch and texture. They are tall, ovoid to pear-shaped, and consist of two or three nerve fibers meandering upward through a fluid-filled capsule of flattened Schwann cells. They are mechanically linked to the edges of the dermal papillae of the skin. Tactile corpuscles are especially concentrated in sensitive hairless areas such as the fingertips, palms, eyelids, lips, nipples, and genitals. Drag your fingernail lightly across the back of your hand, and then across your palm. The difference you perceive is due to the high concentration of tactile corpuscles in the palmar skin. Tactile corpuscles enable you to tell the difference between silk and sandpaper, for example, by light strokes of your fingertips.
- **End bulbs (Krause⁴ end bulbs)** are functionally similar to tactile corpuscles, but instead of occurring in the skin, they are found in the mucous membranes of the lips and tongue, in the conjunctiva on the anterior surface of the eye, and in the epineurium of large nerves. They are ovoid bodies composed of a connective tissue sheath around a sensory nerve fiber.
- **Bulbous (Ruffini⁵) corpuscles** are tonic receptors for heavy touch, pressure, stretching of the skin, deformation of the fingernails, and joint movements. They aid in our perception of the shapes of objects held in the fingers. They are flattened, elongated capsules containing a few myelinated axons in an incomplete fibrous capsule. They're located in the der-

mis, subcutaneous tissue, and joint capsules. They connect the subcutaneous tissues to skin folds in the joints and palms and beneath the fingernails.

- **Lamellar (pacinian⁶) corpuscles** are phasic receptors chiefly for vibration and pressure. They are large ovoid receptors, up to 1 or 2 mm long, found in the periosteum of bones; in joint capsules; in the pancreas and some other viscera; and deep in the dermis, especially on the hands, feet, breasts, and genitals. They consist of a single dendrite running through the core of the organ, encapsulated by multiple concentric layers of cells. The innermost capsule layers are flattened Schwann cells, but the greater bulk of the capsule consists of concentric layers of fibroblasts with narrow fluid-filled spaces between them. In cross section, a lamellar corpuscle looks like an onion slice with a dot, the dendrite, in the middle. Lamellar corpuscles are phasic receptors that respond with one or two action potentials when pressure is applied to them and again when the pressure is taken away, but not in between. They are usually considered to function as vibration receptors, stimulated by such actions as stroking a surface with the fingertips. The friction ridges of the fingertips enhance the vibration and sensitivity of the lamellar corpuscles. In the feet, they contribute pressure sensitivity in the soles and toes that is important in the ability to walk, run, and maintain balance. The toenails provide resistance on the upper side of the toes that enhances the sensitivity of lamellar corpuscles on the lower side.

The other two encapsulated nerve endings in figure 16.2—muscle spindles and tendon organs—have already been discussed in relation to muscle reflexes in section 13.3.

16.2c Somatosensory Projection Pathways

Sensory projection is the transmission of information from a receptor, or a receptive field, to a specific locality in the cerebral cortex, enabling the brain to detect and identify the stimulus. The identifiable origin can be a small and specific area within a receptor, such as a small area of the retina or the skin. The pathways followed by sensory signals to their ultimate destinations in the CNS are called **projection pathways**. From the receptor to the final destination in the brain, most somatosensory signals travel by way of three neurons called the **first-, second-, and third-order neurons**. Their axons are called first- through third-order nerve fibers. The first-order fibers for touch, pressure, and proprioception are large, myelinated, and fast; those for heat and cold are small, unmyelinated or lightly myelinated, and slower.

Somatosensory signals from the head, such as facial senses, travel by way of several cranial nerves (especially CN V, the trigeminal nerve) to the pons and medulla oblongata. In the brainstem, the first-order fibers of these neurons synapse with second-order neurons that decussate and lead to the contralateral thalamus. Third-order neurons then complete the projection pathway to the cerebrum. Proprioceptive signals from the head are an exception, as the second-order fibers carry these signals to the cerebellum.

Below the head, the first-order fibers enter the posterior horn of the spinal cord. Signals ascend the cord in the spinothalamic and

⁵Filippo Ruffini (1812–83), Italian anatomist

⁶Filippo Pacini (1812–83), Italian anatomist

other pathways detailed in table 13.1 and figure 13.6. These pathways decussate either at or near the point of entry into the cord, or in the brainstem, so the primary somatosensory cortex in each cerebral hemisphere receives signals from the contralateral side of the body.

Signals for proprioception below the head travel up the spino-cerebellar tracts to the cerebellum. Signals from the thoracic and abdominal viscera travel to the medulla oblongata by way of sensory fibers in the vagus nerve (CN X). Visceral pain signals also ascend the spinal cord in the gracile fasciculus.

16.2d Pain

From a clinical standpoint, the sense of pain arguably deserves the most attention of all the senses we cover in this chapter, for it is the number one reason people seek medical attention. It is also one of the most difficult problems to treat.

Pain can be defined as an unpleasant perception of actual or potential tissue damage. It isn't a disease in itself, but a symptom of an underlying condition. Its function is to motivate one to avoid, minimize, or escape danger—for example, by favoring a sprained ankle, withdrawing one's hand from a burn, or avoiding things that have caused pain in the past. Few of us enjoy pain and we may wish that no such thing existed, but it is an adaptive and necessary sense—we'd be far worse off without it. We see evidence of this in such diseases as leprosy and diabetes mellitus, where nerve damage (*peripheral neuropathy*) can deaden the sense of pain and make a person unaware of minor injuries or not care enough about them. The resulting neglect can allow injuries to become gangrenous and cost people their fingers, toes, feet, or entire limbs.

Types of Pain

There are two clinical categories of pain—*nociceptive* and *neuropathic*. **Nociceptive pain** stems from tissue injury such as cuts, burns, and chemical irritation, detected by the nerve endings called nociceptors. These are especially abundant in the skin and mucous membranes and occur in nearly all organs, although not in the brain or liver. In some brain surgery, the patient must be conscious and able to talk with the surgeon; such patients need only local anesthesia. Nociceptors occur in the meninges, however, and play an important role in headaches. Nociceptive pain is associated with tissue inflammation and responds to anti-inflammatory drugs such as aspirin, ibuprofen, and naproxen.

Nociceptive pain is subdivided into three kinds according to origin:

1. **Visceral pain**, which arises from the internal organs of the body cavities. This type of pain is diffuse, dull, and hard to locate. Among its causes are stretch (such as an overfull bladder or stomach), chemical irritation (as in intestinal cramps and acid reflux), and ischemia (deficient blood flow, as in heart attacks and menstrual cramps). It is often associated with feelings of squeezing, cramping, and nausea.
2. **Deep somatic pain**, which arises from bones, joints, muscles, and related sources. Examples include the pain of arthritis, sprains, and bone fractures. It often results from excessive stretch (as in an ankle sprain or pulled muscle), but can have other causes.
3. **Superficial somatic pain**, which usually arises from the skin. Examples include the pain of cuts, burns, and insect stings.

Neuropathic pain stems from injuries to the nerves, spinal cord, meninges, or brain. It is often perceived as a stabbing, burning, tingling, or “electrical” feeling. Examples include headache; phantom limb pain; fibromyalgia; and the pain of multiple sclerosis, postherpetic neuralgia (see Deeper Insight 13.3), and cancer (from tumor invasion of nerves or neurotoxic effects of chemotherapy).

Two types of nerve fibers mediate pain responses and contrasting qualities of pain called *fast pain* and *slow pain*. **Fast pain** is the immediate, sharp pain one feels from a cut, burn, or bee sting, for example. It is mediated by myelinated *A-delta* ($A\delta$) nerve fibers. These conduct signals at speeds of 12 to 30 m/s, so the pain is felt quickly upon injury. It is a sharp, localized, often stabbing feel. It is described as *discriminative pain* because we can usually tell exactly where it's coming from. **Slow pain** originates in small unmyelinated *type C* nerve fibers, which conduct at only 0.5 to 2.0 m/s. It has a delayed and more burning, dull, or aching feel, and it's harder to tell exactly where the pain is coming from. If you bang your shin on a piece of furniture, you may feel both of these: a sharp fast pain immediately, then after a few seconds, an even more intense and longer-lasting slow pain.

Projection Pathways for Pain

It is notoriously difficult for clinicians to locate the origin of a patient's pain, because pain travels by diverse and complex routes and the sensation can originate anywhere along the way. Pain signals reach the brain by two main pathways:

1. Signals from the head travel to the brainstem by way of four cranial nerves: mainly the trigeminal (CN V), but also the facial (CN VII), glossopharyngeal (CN IX), and vagus (CN X) nerves. Trigeminal fibers enter the pons and descend to synapses in the medulla. Pain fibers of the other three cranial nerves lead directly to the medulla. Second-order neurons arise in the medulla and ascend to the thalamus, which relays the message to the cerebral cortex, as detailed shortly.
2. Pain signals from the neck and below travel by way of three ascending spinal cord tracts: the spinothalamic tract, spinoreticular tract, and gracile fasciculus (**fig. 16.3**; see also fig. 13.6). The spinothalamic tract carries most of the somatic pain signals that ultimately reach the cortex and make us conscious of pain. The spinoreticular tract carries signals to the reticular formation of the brainstem, and these are ultimately relayed to the hypothalamus and limbic system. Here, they activate visceral, emotional, and behavioral reactions such as nausea, fear, and some reflexes. The gracile fasciculus carries signals to the thalamus for visceral pain, such as the pain of a stomachache or from passing a kidney stone.

When the thalamus receives pain signals from these sources, it relays most of them through third-order neurons to their final destination in the postcentral gyrus of the cerebrum. This is the site of discriminative pain perception—judgment of the location of injury and the quality and intensity of the perception. Exactly what part of this gyrus receives the signals depends on where the pain originated, as described by the concept of somatotopy in section 14.5f (see fig. 14.21). Most of this gyrus is somatosensory. A region of the gyrus deep within the lateral sulcus of the brain, however, is a viscerosensory area, which receives the visceral signals conveyed by

FIGURE 16.3 Projection Pathways for Pain. A first-order nerve fiber conducts a pain signal to the posterior horn of the spinal cord, a second-order fiber conducts it to the thalamus, and a third-order fiber conducts it to the cerebral cortex. Signals from the spinothalamic tract pass through the thalamus. Signals from the spinoreticular tract bypass the thalamus on the way to the sensory cortex.

the gracile fasciculus. The emotional aspects of pain register in the hypothalamus and the prefrontal cortex, limbic system, insula, and anterior cingulate gyrus of the cerebrum (see figs. 14.16, 14.17).

Pain in the viscera is often mistakenly thought to come from the skin or other superficial sites—for example, the pain of a heart attack is felt “radiating” along the left shoulder and medial side of the arm (**fig. 16.4**). This phenomenon, called **referred pain**, results from the convergence of neural pathways in the CNS. In the case of cardiac pain, for example, spinal cord segments T1 to T5 receive input from the heart as well as from the chest and arm. Pain fibers from the heart and skin in this region converge and follow the same pathway from here to the thalamus and cerebral cortex. The brain can’t distinguish which source the arriving signals are coming from. It acts as if it assumes they are most likely from the skin, since skin has more pain receptors than the heart and suffers injury more often. Knowledge of the origins of referred pain is important for the diagnosis of organ dysfunctions.

CNS Modulation of Pain

Regardless of expressions such as “pain in the joints” and “muscle pain,” it must be realized that pain doesn’t exist in these peripheral locations, but only in the brain; it is a conscious *perception* of signals from other organs. Because of this, it is subjective, highly variable, and influenced by a person’s physical and mental state—for example, one’s expectation of pain, fixation on it, or conversely, achieving pain relief by redirecting one’s attention to distractors. This is why such techniques as acupuncture, meditation, hypnosis, placebos, exercise therapy, and Lamaze childbirth can effectively lessen pain.

Some examples show how pain originates in cerebral perception and not in the outlying organs. **Fibromyalgia** is a syndrome of sometimes excruciating, even disabling pain that seems to come from the muscles or bones; yet those distant organs are sending no abnormal nerve signals to the brain. The pain lies entirely in the brain’s abnormal responses to normal incoming signals.

(a)

(b)

FIGURE 16.4 Referred Pain. (a) Areas of referred pain. Pain in these areas of the skin is often a symptom of problems in the indicated viscera. (b) The basis of referred pain in a heart attack.

Phantom limb pain is an eerie perception of pain, sometimes intense, coming from a limb that has been lost by trauma or amputation. It is commonly accompanied by nonpainful *phantom limb sensations* such as the bulk and weight of the absent limb; or feelings of touch, itching, tingling, pressure, heat, or cold; or the illusion that one can even control the limb. Phantom pain can also occur when other body parts have been removed, such as after a tooth extraction or mastectomy. The neurological mechanism of phantom limb pain isn't known with certainty, and it doesn't respond to conventional pain medications. One might think that cutting nerves or even the spinal cord along pain pathways could eliminate the pain, but it doesn't. Battlefield trauma, in contrast to these other cases, shows strikingly how the brain can powerfully suppress the painful awareness of severe injury—many mortally wounded soldiers have reported little or no pain even in their dying hour. So as one neurologist has put it, the bane of pain lies mainly in the brain.

The central nervous system has **analgesic**⁷ (pain-relieving) mechanisms related to the long-known analgesic effects of opium, morphine, and heroin. In 1974, neurophysiologists discovered receptor sites in the brain for these drugs. Since these opiates don't occur naturally in the body, physiologists wondered what normally binds to such receptors. They soon found two analgesic oligopeptides with 200 times the potency of morphine, and named them

enkephalins.⁸ Larger analgesic neuropeptides, the **endorphins**⁹ and **dynorphins**,¹⁰ were discovered later. All three are known as **endogenous opioids** (which means “internally produced opium-like substances”).

These opioids are secreted by the CNS, pituitary gland, digestive tract, and other organs in states of stress or exercise. In the CNS, they're found especially in the central gray substance of the midbrain (see fig. 14.9a) and posterior horn of the spinal cord. They are *neuromodulators* that can block the transmission of pain signals and produce feelings of pleasure and euphoria. Their secretion rises sharply in women giving birth, and they may even be responsible for the aforementioned battlefield reports. However, efforts to employ them in pain therapy have been disappointing.

How do these opioids block pain? For pain to be perceived, signals from the nociceptors must get beyond the posterior horn of the spinal cord and travel to the brain. Through mechanisms called **spinal gating**, pain signals can be stopped at the posterior horn. Two of these mechanisms are described here.

One of these involves **descending analgesic fibers**—nerve fibers that arise in the brainstem, travel down the spinal cord in the reticulospinal tract, and block pain signals from traveling to the brain. **Figure 16.5** depicts one relatively simple mechanism of

⁷an = without; alges = pain

⁸en = within; kephal = head

⁹acronym from *endogenous morphine*

¹⁰dyn = pain

FIGURE 16.5 Spinal Gating of Pain Signals.

pain modulation in the posterior horn. The normal route of pain transmission is indicated by the red arrows and steps 1 through 3:

- 1 A nociceptor stimulates a second-order neuron. The neurotransmitter at this synapse is called **substance P** (think *P* for “pain”¹¹).
- 2 The second-order neuron relays signals up the spinothalamic tract to the thalamus.
- 3 The thalamus relays the signals through a third-order neuron to the cerebral cortex, where one becomes conscious of pain.

The pathway for pain modulation is indicated by descending green arrows and steps 4 through 8:

- 4 Signals from the hypothalamus and cerebral cortex feed into the central gray substance of the midbrain, allowing both autonomic and conscious effects on pain perception.
- 5 The midbrain relays signals to certain nuclei in the reticular formation of the medulla oblongata.
- 6 The medulla issues descending, serotonin-secreting analgesic fibers to the spinal cord. These fibers travel the reticulospinal tract and end in the posterior horn at all levels of the cord.
- 7 In the posterior horn, some of these descending analgesic fibers synapse on short spinal interneurons, which in turn synapse on the second-order pain fiber. These interneurons secrete enkephalins to inhibit the second-order neuron. This is an example of postsynaptic inhibition, working on the downstream side of the synapse between the first- and second-order pain neurons.
- 8 Some fibers from the medulla also exert presynaptic inhibition, synapsing on the axons of the nociceptors and blocking the release of substance P.

Another mechanism of spinal gating is one you may often have consciously employed without knowing why it worked. Have you ever banged your elbow on the edge of a table, burned yourself on a hot cooking pot, or pinched your finger in a door and found that you could ease the pain by shaking your hand or massaging the injured area? This works because shaking or rubbing the area stimulates mechanoreceptors in the skin and deeper tissues and triggers signals in large type A myelinated nerve fibers. These lead to pain-inhibiting interneurons in the spinal cord, like the one at step 7, stimulating them to secrete enkephalins and block the pain signal from ascending to the brain.

The clinical management of pain has had a particularly interesting history, some of which is retold in Deeper Insight 16.4 at the end of this chapter.

BEFORE YOU GO ON

Answer the following questions to test your understanding of the preceding section:

7. What stimulus modalities are detected by free nerve endings?
8. Name any four encapsulated nerve endings and identify their stimulus modalities.
9. Where do most second-order somatosensory neurons synapse with third-order neurons?

¹¹named *substance P* because it was first discovered in a powdered extract of brain and intestine

10. Distinguish between nociceptive and neuropathic pain, and describe the three categories of nociceptive pain.
11. Outline the pathways that pain signals take to and within the brain.
12. Describe two ways that the CNS can modify a person's perception of incoming pain signals.

16.3 The Chemical Senses

Expected Learning Outcomes

When you have completed this section, you should be able to

- a. explain how taste and smell receptors are stimulated; and
- b. describe the receptors and projection pathways for these two senses.

Taste and smell are the chemical senses. In both cases, environmental chemicals stimulate sensory cells and trigger nerve signals in certain cranial nerves. Other chemoreceptors, not discussed in this section, are located in the brain and blood vessels and monitor the chemistry of the body fluids. Taste and smell not only influence our acceptance or rejection of food, but also activate gastric secretion and blood flow in preparation for digestion, and stimulate insulin secretion to promote nutrient metabolism.

16.3a Gustation—The Sense of Taste

Gustation is a sensory perception of molecules dissolved in water that come in contact with an organism's sensory receptors. It is crucial to the survival of organisms from the lowliest of microbes to humans, especially in the selection of suitable food and drink. Why do humans prefer certain tastes? Evolutionarily, seeking foods with high nutrient quality and avoiding food that may be toxic are adaptive for survival. For our hunter–gatherer ancestors who rarely had access to sugary, salty, fatty foods, it was advantageous to seek sweet, salty, and savory tastes. In industrialized societies, many people are overly sedentary and have access to cheap, abundant, sugary, salty, and fatty foods. The motivation to seek out such tastes has become maladaptive for many—contrary to health—and associated with obesity and other diseases that plague our modern lives.

Gustation begins with the chemical stimulation of sensory cells clustered in about 4,000 **taste buds**. The chemical stimuli are called **tastants**.

Anatomy

The visible bumps on the tongue are not taste buds but **lingual papillae**. There are four types of papillae—one without taste buds and three with taste buds just beneath the epithelial surface, where they're not visible to the eye (**fig. 16.6**):

1. **Filiform¹² papillae** are small spikes without taste buds. They are responsible for the rough feel of a cat's tongue and are important to many mammals for grooming the fur. They are

¹²*fili* = thread; *form* = shaped

FIGURE 16.6 Gustatory (Taste) Receptors. (a) Superior surface of the tongue and locations of its papillae. (b) Detail of the vallate papillae. (c) Taste buds on the walls of two adjacent foliate papillae. (d) Structure of a taste bud. **APR**

c: Jose Luis Calvo/Shutterstock

the most abundant papillae on the human tongue and are concentrated especially at the tip, its most mobile part. By enhancing friction in this region, they may aid in the tongue's manipulation of food. They are innervated and serve in one's sense of food texture, called *mouthfeel*. They're important not only in the acceptance or rejection of food, but sensing when one has chewed food enough to swallow it.

2. **Foliate¹³ papillae** are also weakly developed in humans. They form parallel ridges on the sides of the tongue about two-thirds of the way back from the tip, adjacent to the molar and premolar teeth, where most chewing occurs and most flavor chemicals are released from the food. Most of their taste buds degenerate by the age of 2 or 3 years. This may partially explain why children so often reject foods that are tolerated or enjoyed by adults.

3. **Fungiform¹⁴ papillae** (FUN-jih-form) are shaped somewhat like mushrooms. Each has about three taste buds, located mainly on the apex. These papillae are widely distributed, but especially concentrated at the tip and sides of the tongue. These respond not only to taste but, like filiform papillae, also to food texture.
4. **Vallate¹⁵ papillae** are large papillae arranged in a V at the rear of the tongue. Each is surrounded by a deep circular trench, like a moat. Glands in the root of the tongue continually secrete saliva into the trench and flush it out. This keeps old tastants from lingering too long around the papilla's taste buds and makes the taste cells more responsive to new flavors introduced in the saliva. There are only 7 to 12 vallate papillae, but they contain up to half of all taste buds—around 250 each, located on the walls of the papilla facing the trench.

¹³*foli* = leaf; *ate* = like

¹⁴*fungi* = mushroom; *form* = shaped

¹⁵*vall* = wall; *ate* = like, possessing

Most taste buds are on the tongue, but some occur inside the cheeks and in the soft palate, pharynx, epiglottis, and upper esophagus, especially in infants and children. Regardless of their location, though, all taste buds look alike (**fig. 16.6c, d**). Their shape and layering of cells resemble a garlic bulb. They include 50 to 100 *taste cells*, *supporting cells*, and *basal cells*. The taste cells are shaped somewhat like individual cloves within a garlic bulb. They have a tuft of apical microvilli called **taste hairs**, which serve as receptor surfaces for tastants. The hairs project into a pit called a **taste pore** on the epithelial surface of the tongue. Taste cells are epithelial cells, not neurons, but they synapse with sensory nerve endings at their base, where they have synaptic vesicles and release neurotransmitters. A taste cell lives for only 9 to 15 days. **Basal cells** are stem cells that multiply and replace taste cells that have died, but they also synapse with sensory nerve endings of the taste bud and may play some role in the processing of sensory information before the signal goes to the brain. **Supporting cells** are curved, flattened cells shaped like barrel staves. Most form a supportive capsule around the perimeter of the taste bud, but some occur between the taste cells. They have no synaptic vesicles or sensory role.

Physiology

To be tasted, molecules must dissolve in the saliva and flood the taste pore. On a dry tongue, sugar and salt have as little taste as a sprinkle of sand. Physiologists currently recognize at least five primary tastes, itemized below. All of these are detected throughout the tongue; physiologists long ago abandoned the old concept of a taste map of the tongue that supposedly showed regional specialization of taste buds for different tastes. The primary tastes are as follows:

1. **Salty**, produced by metal ions such as sodium and potassium. Since salts are vital electrolytes, there is obvious value in our ability to taste them and in having an appetite for salt. Electrolyte intake is also important in the osmotic regulation of the body's fluid balance. Electrolyte deficiencies can cause a craving for salt; many animals as diverse as insects, parrots, deer, and elephants seek salt deposits ranging from mud puddles and wet clay to the sweat on larger animals and people. Pregnancy can lower a woman's electrolyte concentrations and create a craving for salty food.
2. **Sweet**, produced by many organic compounds, especially sugars. Sweetness is associated with carbohydrates and foods of high caloric value. Many flowering plants have evolved sweet nectar and fruits that entice animals to eat them and disperse their pollen and seeds. Our fondness for fruit and sugar has coevolved with plant reproductive strategies.
3. **Umami**¹⁶ is a meaty or savory taste produced by amino acids such as aspartic and glutamic acids—the taste of beef or chicken broth, cheese, and mushrooms. The umami taste motivates protein intake.
4. **Sour**, usually associated with acids in such foods as citrus fruits. Sour is usually an aversive taste that helps one avoid spoiled foods and overloading the body's acid–base balance.
5. **Bitter**, associated with spoiled foods and alkaloids such as nicotine, caffeine, quinine, and morphine. The threshold for bitter is

lowest of all—that is, we can taste lower concentrations of alkaloids than of acids, salts, and sugars. This is perhaps a protective sense; alkaloids are often poisonous and the bitter sensation usually causes a person or animal to reject an item as food. While flowering plants make their fruits temptingly sweet, they often load their leaves with bitter alkaloids to deter animals from eating them. However, many bitter compounds are not very toxic, and many toxic compounds in nature are not bitter. There is little correlation between bitterness and toxicity, so the sense of bitter taste is suspected of having other functions not yet discovered. The same receptor for bitter found in the mouth has also been found in the small intestine, trachea, and elsewhere, suggesting a broader function. One function seems to be to elicit adaptive responses in the digestive tract to the different foods we swallow. Humans have about 25 genes for different bitter receptors alone.

The first three of these tastes reinforce the appetite and desire for fundamental classes of nutrients—minerals, carbohydrates, and proteins. Sour and bitter are usually aversive stimuli that discourage the ingestion of potentially harmful substances, but many of us cultivate a taste for sour and bitter foods such as lemons, yogurt, turnip greens, and Brussels sprouts. Variations between people in the taste for such substances has at least a partial genetic basis.

Two important categories of nutrients not included in this classical list are fats and water. Recent research suggests that two more primary tastes may warrant inclusion in the list, as they each have their own unique oropharyngeal receptors: **oleogustus**,¹⁷ a proposed name for the taste of fats, and **water** (if one considers that a taste).

The many flavors we perceive aren't simply a mixture of these primary tastes, but are also influenced by food and beverage temperature, sound (such as fizz or crunch), texture (chewy, flaky, creamy), aroma, temperature, appearance, and one's state of mind, among other things. Many flavors depend on smell; without their aromas, cinnamon merely has a faintly sweet taste, coffee and peppermint are bitter, and apples and onions taste almost identical. Some flavors such as pepper are due to stimulation of free endings of the trigeminal nerve rather than taste buds. Filiform and fungiform papillae of the tongue are innervated by the *lingual nerve* (a branch of the trigeminal) and are sensitive to texture.

Sugars, alkaloids, and glutamate stimulate taste cells by binding to receptors on the cell surface, which then activate G proteins and second-messenger systems within the cell. Sodium and acids penetrate into the cell and depolarize it directly. By either mechanism, taste cells then release neurotransmitters that stimulate the sensory dendrites at their base.

Taste cells within a single taste bud communicate with each other through gap junctions and chemical signals to process gustatory information before transmitting signals to the brain. They also secrete hormones that signal the stomach, pancreas, and other digestive organs in advance to process, in different ways, whatever food we are about to swallow.

Projection Pathways

The facial nerve (CN VII) collects sensory information from taste buds of the anterior two-thirds of the tongue, the glossopharyngeal

¹⁶delicious, yummy (Japanese slang)

¹⁷*oleo* = oil; *gust* = taste

nerve (CN IX) from the posterior one-third, and the vagus nerve (CN X) from taste buds of the palate, pharynx, and epiglottis. All taste fibers project to a site in the medulla oblongata called the *solitary nucleus*. Second-order neurons arise here and relay the signals to two destinations: (1) nuclei in the hypothalamus and amygdala that activate autonomic reflexes such as salivation, gagging, and vomiting, and that function in emotions and memory associated with taste; and (2) the thalamus, which relays signals to the primary gustatory cortex, located in the insula and roof of the lateral sulcus of the cerebrum, where we become conscious of the taste. Processed signals are further relayed to the orbitofrontal cortex (see fig. 14.16), where they are integrated with signals from the nose and eyes and we form an overall impression of the flavor and palatability of food.

16.3b Olfaction—The Sense of Smell

Olfaction, the sense of smell, is a response to airborne chemicals called **odorants**. Human behavior is influenced by smell in both obvious ways and subtle, often unconscious ones. It plays a key role in food selection as we've already noted. It is important in avoiding hazards, ranging from a primitive aversion to excrement or decaying flesh to modern awareness of a gas leak or chemical irritant. It is involved in unconscious communication between persons, where it influences mate choice and parent–infant bonding. Smell is closely tied to memories and emotion. Decreased ability to smell is an early predictor of Alzheimer disease, and olfactory dysfunction due to disease or injury is associated with depression.

Odors are detected by receptor cells in a patch of epithelium, the **olfactory mucosa**, in the roof of the nasal cavity (fig. 16.7). This location places the olfactory cells close to the brain, but it isn't as well ventilated as the lower nasal cavity; forcible sniffing is often needed to identify an odor or locate its source.

Anatomy

The olfactory mucosa covers about 5 cm² of the superior concha, cribriform plate, and nasal septum of each nasal fossa. It consists of 10 to 20 million **olfactory cells** as well as epithelial supporting cells and basal stem cells. The rest of the nasal cavity is lined by a nonsensory *respiratory mucosa*.

Unlike taste cells, which are epithelial, olfactory cells are neurons. They are shaped a little like bowling pins (fig. 16.7c). The widest part, the cell body, contains the nucleus. The neck and head of the cell are a modified dendrite with a swollen tip. The head bears 10 to 20 cilia called **olfactory hairs**. These cilia are immobile, but they have binding sites for odor molecules. They lie in a tangled mass embedded in a thin layer of mucus. The basal end of each cell tapers to become an axon. These axons collect into small fascicles that leave the nasal cavity through pores (*cribriform foramina*) in the ethmoid bone. Collectively, the fascicles are regarded as the olfactory nerve (CN I).

Olfactory cells are the only neurons directly exposed to the external environment. Apparently this is hard on them, because they have a life span of only 60 days. Unlike most neurons, however, they're replaceable. The basal cells continually divide and differentiate into new olfactory cells.

Physiology

Humans do not, as commonly supposed, have a poorer sense of smell than other mammals. That notion arose from certain unsubstantiated nineteenth-century assumptions of Paul Broca and Sigmund Freud and suffered from confirmation bias in twentieth-century and even more recent research. We have only about one-third as many functional olfactory genes as rodents do, but we have more complex olfactory bulbs and orbitofrontal cortex—the brain regions where odor signals are interpreted. Humans outperform rodents and dogs for some odors and underperform them for others. Our sense of smell is much more sensitive than our sense of taste; we can detect odorant concentrations in the air as low as a few parts per trillion.
